Preface

This report on "Environmental improvement potential of residential buildings" is a scientific contribution of the JRC to the European Commission's Integrated Product Policy framework which seeks to minimise the environmental degradation caused the life cycle of products. A previous study coordinated by the JRC (EIPRO study) had shown that building occupancy and structure all together make up 20 to 35% of the impacts of all products for most impact categories.

This report presents a systematic overview of the environmental life cycle impacts of residential buildings in EU-25. It also provides an analysis of the technical improvement options that could be help reducing these environmental impacts, with a special focus to their main source, namely energy use for space heating. The report assesses the environmental benefits and the costs associated with these improvement options.

Executive summary

Introduction

In June 2003, the European Commission adopted the Communication on Integrated Product Policy (IPP) [COM(2003) 302 FINAL] with the aim of reducing the environmental impacts from products and services throughout their life cycle. In this context, the EIPRO study was carried out and was concluded in May 2006 [EIPRO 2006]. The study showed that products from only three areas of consumption – food and drink, private transportation, and housing – are responsible for 70-80% of environmental impacts of private consumption and account for some 60% of consumption expenditure altogether.

The conclusions of the EIPRO study thus suggested initiating a more in-depth analysis of these three groups of products. To this end, three parallel projects were launched and coordinated by the IPTS in order to analyse the environmental IMprovement of PROducts (IMPRO, respectively IMPRO-Car, IMPRO-Meat, and IMPRO-Building projects).

This report, which presents the IMPRO-Building project results, is based on a research carried out by the JRC (IPTS) and supported by a study conducted by Lehrstuhl für Bauphysik LBP, CalCon Holding GmbH, and PE International GmbH.

Objectives and general approach

The overall goal of the IMPRO-Building project was the analysis of the environmental improvement potentials of residential buildings, including all relevant types of buildings used as household dwellings, from single-family houses to multi-apartment buildings, including existing and new dwellings in the EU-25. This has been achieved through:

- the estimation and the comparison of the life cycle environmental impacts of residential buildings
- the identification of the main environmental improvement options and their analysis in terms of their environmental benefits and of their costs.

The environmental impacts were analysed both for building structures and building occupancy. As concerns the improvement options, only those affecting the building structure and design¹ changes were considered.

The research was structured along three steps:

- 1. Define an appropriate building stock typology and provide its characterization regarding several aspects (e.g. population and residential area, building type, age, structure) and define building models that are the most "representative" buildings for the EU-25.
- 2. Analyse the life cycle impacts of the different building models and identify the environmental hotspots.
- 3. Identify the improvement options and analyse their environmental effects and their costs.

¹ This term indicates the general and common layout of residential buildings with common building elements.

Overview of residential buildings in the EU-25

The first step was primarily based on existing data and information taken from previous EUfunded projects and expertise in various EU countries regarding the most relevant aspects of buildings (e.g. structure, age, energy efficiency). The approach used to derive a list of relevant building models was guided by the need to reach sufficient representativeness of the building stock at EU-25 level while also keeping a reasonable level of study feasibility.

In order to ensure a sufficient level of representativeness, several criteria were considered, including population, total construction area per building type, common building structures, and weather conditions. The available country specific data on buildings and dwellings, including the segmentation into building types and age have been thoroughly reviewed.

This led to building models distributed into three building types: single-family houses (including two-family houses and terraced houses), multi-family houses, and high-rise buildings. These three building types represent 53%, 37% and 10% respectively of the existing EU-25 building stock. The buildings were also defined in such a way as to be distributed into three main zones in Europe that roughly represent three climate zones according to heating degree days (HDD).

The 72 selected building models (53 existing buildings and 19 new building types), were assessed to be representative of about 80% of the residential building stock in the EU-25. They were described in terms of their building stock representativity, geographical distribution, size, age, design, residual lifespan, and thermal insulation. The description also covered the material composition of the different building elements (roofs, external and interior walls, basement/foundation, floors, windows/doors).

 Table A
 Number of buildings types in each zone

Life cycle environmental impacts

The process chain approach was implemented in order to quantify the life cycle impacts of the different building models. The functional unit of the LCA is the use of 1 m² of the building's living area over a 1 year period.

The general system boundary was set similar for all new building types, including respectively the production and transport of building materials, the building refurbishment, building space heating, and cooling and waste management (demolition and refurbishment).

Regarding buildings, the life cycle phase "production and transport of building materials" was disregarded as it had occurred and cannot therefore be subjected to any improvement.

The considered environmental impact categories were selected based on scientific robustness, relevance and practicability. These are acidification, eutrophication, climate change, ozone

layer depletion, and photochemical pollution. The primary energy consumption was also quantified.

For each impact category, the corresponding cumulated substance flows were quantified and aggregated to the so-called "mid-point" indicators (e.g. carbon dioxide, methane, N₂O and other greenhouse gas emissions were aggregated into CO_2 equivalent emissions in accordance with the respective global warming potentials).

For each existing building, a residual service lifespan was estimated by expert judgement, and limited to a maximum of 40 years. For new building types, this limit was also applied in order to take into account the uncertainties inherent to the long term and to keep the time horizon consistent with what policy measures can cover.

The background datasets were taken from two main sources of data:

- the GaBi 4 database [LBP & PE 2007] provided data on the construction, refurbishment and waste treatment processes
- the software programme epiqr® was used to calculate the energy demand for space heating, applying a calculation method based on the European standard EN 832.

A first finding from the life cycle assessment as implemented to the different building models is the similarity of trends shown over the different impact categories when the different building types according to zones are compared. This reflects the important role of energy use in most of the environmental impacts quantified, first as a result of fuel combustion for space heating, and, second, as a result of the industry processes involved in the manufacturing of building products. Consequently, both primary energy use and greenhouse gas (GHG) emissions are good proxy indicators to assess the environmental performance of the buildings.

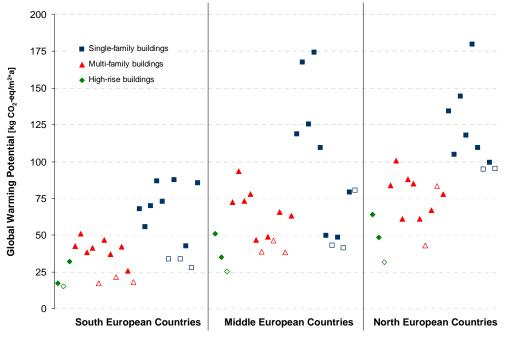

Figure A Life cycle impacts of all building types for the environmental impact category "Global Warming Potential" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

The results also show that new buildings, as currently erected, generally show better environmental performance when compared to existing ones. This is due to the better energy performances achieved as long as the best available practices are applied, especially in terms of building insulation.

Weather conditions obviously entail higher space heating demands, which results in higher energy demands for buildings in northern regions. However, when normalised to similar weather conditions (based on heating degree days), buildings in these zones tend to have the best energy performances. The effect of the buildings geometry was also reflected in the general trend of higher energy demand in single-family houses when compared to the others. Cooling demand was estimated to be currently negligible in the total buildings energy demand.

The use phase of buildings, as dominated by the energy demand for heating is by far the highest for all buildings. For new buildings, the construction phase is also significant and its relative importance varies from one impact category to the other. The end-of-life phase is of much lower importance.

Regarding the use phase, the associated environmental impacts were broken down into the different building elements based on the respective heat losses. This showed that heat losses resulting from ventilation and infiltration have a significant importance for all buildings. This also holds true for external walls, particularly for high-rise buildings. Heat losses through roofs are important for a majority of single-family and multi-family houses. Windows were suggested to be of lower importance. This is partly because the retrofitting of windows was assumed to be part of autonomous improvement, which may, to some extent, provide a too optimistic picture. In general, the variations observed from one building type to another are explained by the geometry and current insulation levels of the buildings.

The use phase was also shown to be most important for new buildings with, however, a lower relative importance as a result of the better energy performance of these buildings. Regarding the new building construction phase, the impacts primarily stem from the construction of the exterior walls, the basement, and floors/ceilings. Interior walls, roof and windows only play a minor role.

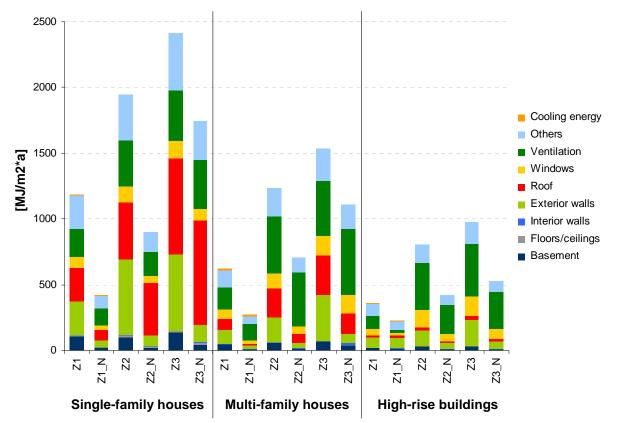

Figure B Contribution of the individual construction elements to the environmental impacts of the Use Phase (total Primary Energy) according to zone and building group (weighted average) _N denotes new buildings

Improvement options

Improvement options for relevant building types were identified, focusing on the environmental hotspots (use phase and construction phase). These were analysed against the initially defined base cases.

For **new building types**, the quantification of environmental benefits was limited to the options that primarily reduce the impacts from the construction phase, which is feasible by changing the material composition of buildings.

The results showed that, amongst the alternatives considered, significant environmental improvements can be expected only when the substitution leads to the use of wood products instead of more "conventional" products (concrete, reinforced concrete, bricks).

Besides these construction alternatives, improvement measures should also be considered with a view to reduce future GHG emissions from the building stock. This includes the new concepts of passive housing and so-called "zero CO_2 emissions buildings" for which the space heating demand is reduced to 20 kWh/m². Their analysis was, however, beyond the scope of this IMPRO-Building project.

For **existing buildings**, consistently with the dominant role of the use phase, the measures address this life cycle part, and particularly space heating, covering "additional roof insulation", "additional façade insulation" and "new sealings to reduce ventilation" whenever the corresponding building element was shown to be an environmental hotspot.

The three measures considered were shown to yield a significant environmental improvement potential, which, for a majority of the buildings types analysed, represented at least 20% greenhouse gas emissions compared to the respective base case. When rescaled to the EU-25 level, the resulting improvement potentials, when measured in terms of CO_2 emissions reduction are high.

For each measure, the highest improvement potentials from the European perspective were derived for zone 2. This is partly due to the larger building stock in use and to the colder climate conditions. The major improvement potentials lie with single-, two-family and terraced houses, followed by multi-family buildings. Despite important percentage reductions potentials for high-rise buildings, smaller emissions reductions are expected in absolute terms due to the smaller share of these buildings in the overall building stock.

When combining and totalling the building types included in the analysis and relevant retrofit measures, the derived total life cycle emission reduction potential reaches 360 Mt CO_2 -eq/a. This corresponded to about 7% of the total direct greenhouse gas emissions in the EU-25 in 2005 (without land use, land use change and forestry) [EEA 2007]. This high estimated emissions reduction potential can be achieved provided that all barriers (e.g. social, economic) are overcome. The initial investment costs may represent one of these barriers. These life cycle costs of the retrofit measures were analysed through the calculated internal return rates and the net present values associated with these retrofit measures.

| Improvement measure | Building group | Zone | Abatement cost | Total improvement potential |
|------------------------|----------------------|--------|-----------------------------|--------------------------------|
| | | | Euro/t CO ₂ -eq. | Mt CO ₂ -eq./a |
| Additional roof | Single-family houses | Zone 1 | -89.84 | 47.67 |
| insulation | | Zone 2 | -92.64 | 83.50 |
| Additional façade | Single-family houses | Zone 1 | 54.51 | 29.46 |
| insulation | | Zone 2 | -18.56 | 64.21 |
| | Multi-family houses | Zone 1 | 12.35 | 8.67 |
| | | Zone 2 | na | na |
| | High-rise buildings | Zone 1 | -55.69 | 6.81 |
| | | Zone 2 | na | na |
| New sealings to | Single-family houses | Zone 1 | -60.35 | 29.71 |
| reduce ventilation | | Zone 2 | na | na |
| | Multi-family houses | Zone 1 | -64.78 | 14.48 |
| | - | Zone 2 | -52.80 | 82.39 |
| | High-rise buildings | Zone 1 | -53.92 | 6.39 |
| | _ | Zone 2 | -54.85 | 6.06 |

 Table B
 Summary of environmental improvement potential and abatement costs

For both roof insulation and reduced ventilation, the measures were shown to be economically profitable (positive net present value and a high internal rate of return) for a majority of buildings. For external wall insulation, the economic profitability is less systematic as, in some cases, the subsequent fuel costs savings do not compensate the higher initial investments. Compared to the two other measures, the application of new sealings in order to reduce ventilation bears smaller improvement potentials but has a higher economic profitability as a result of very low initial investments. It should also be noted that the economically profitability only holds true if the energy savings are granted to the investor.

It was also shown that most of the improvement options are economically viable with costs being smaller than the benefit from energy savings. In total, 80% of the total GHG reduction potential in zone 1 and 95% of the potential in zone 2 can be reached at negative CO_2 abatement costs.

These results provide elements to guide policy making aimed to support the implementation of these measures with instruments such as subsidies, consumer awareness. However the decision on which measures to take for an individual building should be based on a prior assessment which takes into account the individual situation of the building.

Conclusion

Summarizing, it can be stated that the current situation of the European residential buildings stock in terms of environmental performance is far from the currently discussed low-energy standards and there lies a tremendous potential for improvements. If the measures examined are carried out on the buildings considered, the emissions of greenhouse gases from these buildings may be cut by around 30% to 50% over the next 40 years. Therefore, active promotion and strong actions from all stakeholders have to be undertaken in order to seize this environmental opportunity. The information this study provides the basis for discussions on measures and steps that can taken in that direction.

1 Introduction

1.1 Background

In June 2003, the European Commission adopted the Communication on Integrated Product Policy (IPP) [COM(2003) 302 FINAL] with the aim of reducing the environmental impacts from products and services throughout their life-cycle. In this context, the EIPRO study was carried out and was concluded in May 2006 [EIPRO 2006]. The study showed that products from only three areas of consumption – food and drink, private transportation, and housing – together are responsible for 70-80% of environmental impacts of private consumption. These products also account for some 60% of consumption expenditure altogether.

Buildings and construction products have a significant socio-economic relevance. The activities in the building and construction sector have high initial and follow-up expenditures, long life-cycles and require a large amount of materials and energy.

These are already subject to several activities in policy areas and in research. The Energy Performance of Buildings Directive [EPBD] is now being implemented and is beginning to show effects in the construction sector. The Energy using Products Directive [EUP DIRECTIVE] also provides the legal framework for improving the eco-design of energy-related building elements, including e.g. heating and cooling systems used in buildings. It should also be noted that the manufacturers of building materials are increasingly providing life cycle based environmental information on their products as, e.g. environmental product declaration (EPD).

Following the conclusions from the EIPRO study, the project 'Environmental Improvement Potentials of Buildings (IMPRO-Building)' was launched by the JRC (IPTS, Seville), with a view to analyse the life cycle impacts of residential building in the EU-25 and to assess the potentials to improve their environmental performance. The project was supported by a study conducted by Lehrstuhl für Bauphysik LBP, CalCon Holding GmbH, and PE International GmbH.

This report presents the approach followed throughout the IMPRO-Building project, its results and the conclusions drawn.

1.2 Objectives and scope of the IMPRO-Building project

The overall goal of the IMPRO-Building project is the analysis of the environmental improvement potentials of residential buildings. This has been achieved through:

- the estimation and comparison of the environmental life cycle impacts of buildings used as household dwellings
- the identification of the main environmental improvement options related to buildings addressing the different life cycle stages and estimation of the size of the environmental improvement potentials
- the assessment of the feasibility as well as the socio-economic impacts of the identified improvement options.

1

The overall scope of the work involved the environmental impact of the relevant types of buildings used as household dwellings, from single-family houses to multi-apartment buildings, including existing and new dwellings in the EU-25.

Environmental impacts were analysed both for building structures and building occupancy. Regarding the improvement options, only those affecting the building structure and design² changes were considered. Improvement options entailing changes in the heating and cooling system are disregarded³.

For the analysis, a life-cycle approach was applied and all the relevant environmental impact categories for the selected structures were taken into account.

1.3 Report structure

Chapter 2 provides the methodology adopted in the project. An overview of the general approach is first given, followed by a more detailed description of the method used for assessing the environmental impacts of the buildings.

A general overview of the residential buildings in the EU-25 is given in Chapter 3. This explains how the building types modelled in the project were defined and grouped according to zones, size and age in order to identify the main typical and relevant building types.

Chapter 4 contains all relevant information on the life cycle assessment methodology. Based on the environmental impact assessment, the life cycle assessment results are described and discussed in Chapter 5. The environmental hotspots are also identified.

Chapter 6 includes the identification and the description of the improvement options to increase the environmental performance of both existing and new buildings. In Chapter 7, the improvement potentials for the identified measures on a building level and on European level are calculated. The cost efficiency of the improvement options is assessed.

Conclusions for the project are drawn in Chapter 8.

² This term indicates the general and common layout of residential buildings with common building elements.

³ This choice was made to avoid overlapping with studies that were undertaken during the course of the IMPRO-Building project in the framework of the EuP Directive [EuP DIRECTIVE].

2 General approach for the IMPRO-Building project

The research has been structured along the following steps (see Figure 2.1):

- I General overview of residential buildings in the EU-25, definition of the appropriate geographical resolution and selection of representative building types.
- II Detailed analysis of the life cycle impacts of the selected building types.
- III Identification and analysis of the main environmental improvement options.

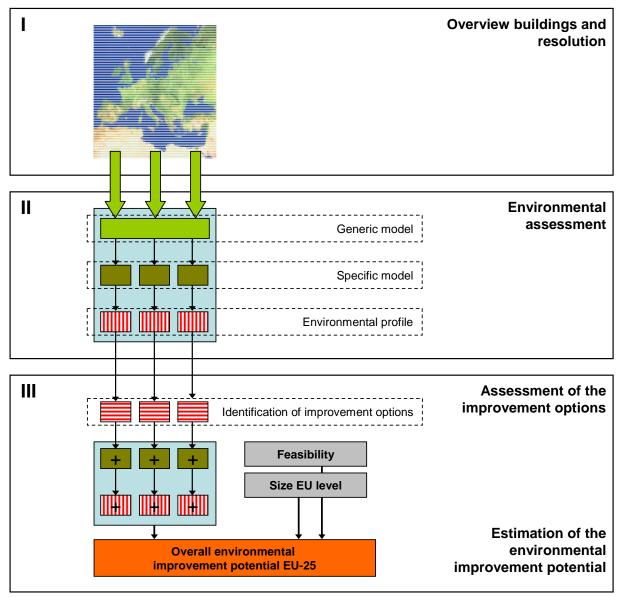

Figure 2.1 Project structure

The first step was built upon existing information, statistical reviews, literature analysis and expert interviews. Several former EU projects represented the main basis used to establish a list of building types representing altogether 80% of the EU-25's residential areas.

The second step started with the definition of the functional unit and system boundaries considered when implementing the life cycle assessment of the different building types which were described according to a common generic model with all relevant necessary parameters and interrelations. The environmental assessment was made in accordance to the ISO standards 14040 and 14044 [EN ISO 14040, EN ISO 14044].

This was the basis for the third step which consisted of the identification of the main environmental improvement options and their assessment and, the cost efficiency of these measures.

3 Overview of residential buildings in the EU-25

The overview of residential buildings in the EU-25 served to define a list of the most representative building types, considering an appropriate geographical resolution. Residential buildings are defined as buildings primarily constructed for residential occupancy. Data were mainly gathered from already accomplished European projects like the COST action C16 [WETZEL & VOGDT 2005], EPIQR [EPIQR 1996] and INVESTIMMO [BAUER ET AL. 2004], that all focused on residential buildings in Europe.

The objectives of all the research work were to provide an overview of impacts and improvement options of residential buildings in Europe. This required a description of the EU-25 building stock and the definition of "typical" residential buildings in order to build a representative set of building models for the project.

Detailed data about country level population and residential buildings stock were the basis for a first definition of buildings according to age and size, and to order these buildings according to their relevance. As an intermediate result, a representative set of building types was derived for each country. These building types were also clustered at a more aggregated level.

For these building types, materials and dimensions were defined. Furthermore, the reference service life of the different construction elements was analysed. In order to allow an analysis of the use phase of the building types, an overview of the different refurbishment and maintenance actions that are conducted, was also elaborated. After some iterations, it was possible to retrieve groups of transnational building types that give a sound overview of the residential stock in the EU-25.

3.1 Definition of the model and database

Each residential building type is based on a specific construction model and a specific material composition. The building types cover the EU-25 residential buildings stock as much as possible. Data have been collected according to the template shown in Table 3.1.

| Table 3.1 | Building type input table |
|-----------|---------------------------|
|-----------|---------------------------|

| Construction elements | Material | Density | Thickness | Area | Volume | Piece | Mass |
|-----------------------|----------|---------|-----------|----------------|----------------|-------|------|
| | - | kg/m³ | m | m ² | m ³ | - | kg |
| Exterior walls | | | | | | | |
| Interior walls | | | | | | | |
| Roof | | | | | | | |
| Floors/Ceilings | | | | | | | |
| Windows/Doors | | | | | | | |
| Basement/Foundation | | | | | | | |

The analysis of the use phase implied using data referring to the heating and cooling energy demand. Since the focus was on the analysis of improvement potentials of building design rather than HVAC (Heating, Ventilating, and Air Conditioning) systems, a standard heating system was defined for all building types. The differences of the space heating demand of the different building types only result from each building's design, construction material

composition and from the climatic region. This was calculated with the European software epiqr® (see detailed description in Section 4.5.3.1).

3.2 Population and building stock

Both population and building stock data sources are Eurostat, some publications from the construction sector and construction product industries, and statistics from financial institutions. The used references are given in Annex E. It has to be noted that some deviations exist between the different data sources, including amongst the official ones. Table 3.2 lists the population of the EU-25 in the descending order.

| Country | 1995 | 1996 | 1997 | 1998 | 1999 | 2000 | 2001 | 2002 | 2003 | 2004 |

Figure 3.1 Example for a statistical overview of the EU-25 countries Source: [EUROSTAT 2006]

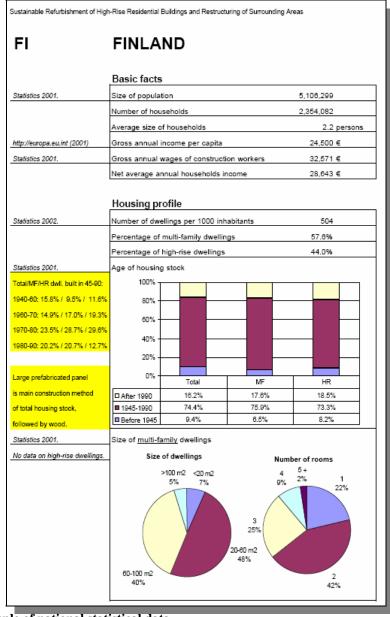

Figure 3.2 Example of national statistical data [VROM 2005]

Very few reports cover all EU-25 countries so different sources, including forecasts about future building production in some countries (see for instance Table 3.3) have been combined.

The analysis of the available statistical data showed some data inconsistencies, even regarding one same country and survey. This is partly explained by different building classifications. For example, commercial buildings also containing some dwellings are sometimes accounted for in the dwellings stock. Another problem is the fact that the definition of "high-rise building" differs from one country to another. In Estonia, for instance, a high-rise building has at least 14 storeys whereas, in south European countries, high-rise buildings are defined as having more than five storeys. In some other countries, the criterion is the height of guttering of the building (e.g. in Germany, a high-rise building is higher than 22 m, as the standardized ladders of the fire-brigades can only reach up to 22 m and therefore other fire protection rules hold).

| Country | Population growth 1990 to 2004 in % | Dwellings stock in 2003 | | Living space per person in 2004 in m ² | |
|-------------------------|---|----------------------------|-----|---|------|

a) CEE5 aggregates the five countries in Central and Eastern Europe: Czech Republic, Slovakia, Hungary, Poland, and Slovenia. Source: [AMANN 2006]

Whenever different sources provided different values, the preference was given to the most elaborated and/or recent one. In some cases, the average value was taken into account.

3.3 Definition of group of buildings according to size

In order to group the European buildings stock into clusters that could subsequently be described in accordance with the datasheets in Table 3.3, the statistical data were further aggregated into three major groups:

- single-family houses (including two-family houses and terraced houses)
- multi-family houses
- high-rise buildings.

Single-family houses include individual houses that are inhabited by one or two families. Also terraced houses are assigned to this group.

Multi-family houses contain more than two dwellings in the house. The separation to the next group – the high-rise buildings – is either not made or made differently from one country to another. It is considered that buildings with fewer than 9 storeys are regarded as multi-family buildings.

High-rise buildings were defined as buildings that are higher than 8 storeys.

One special building type, the panelised structure buildings, is found in most (especially eastern European) countries. In literature and statistics, they are either accounted for amongst high-rise building or multi-family buildings (Figure 3.3).

Figure 3.3 Panel buildings especially erected in the eastern European states Source: [WETZEL & VOGDT 2005]

In the EU-25, altogether 34 million dwellings or 17% of the whole buildings stock are included in panel buildings. In each country where these buildings exist, one to three different building types were defined.

3.4 Definition of groups of buildings according to age

Most of the statistical data considered are produced by Eurostat, covering building types and construction period disaggregation. The "Housing Statistics" report [BOVERKET & MMR 2005] is another important statistical source. The last issue from 2004 is the 10th edition in a series of publications dating back to 1991 and the first to cover 25 Member States.

The data provide building age groupings for all EU-25 countries (Figure 3.4). The data were taken into account for cross-checking the national individual age groups and also were used for defining age groups where no other data were available.

Three age categories for buildings are set as the highest aggregated level for each country:

- until 1945 (old buildings)
- between 1946 until 1990 (post war buildings)
- after 1991 (current and new buildings).

It is possible to identify typical construction systems in some countries or zones and for certain periods. It has to be noted that besides some factors such as population and economic growth, the building activities are also heavily influenced by the national housing policy and the funding policy.

The grouping into the three age categories can be seen as a way to simplify the overview but may mask such specificities. Some of the identified building types especially show an overlapping of these age groups, meaning that one building type represents buildings from the other groups, e.g. the group of the "post war buildings" (1945 – 1990) and the "current and new buildings" (after 1990).

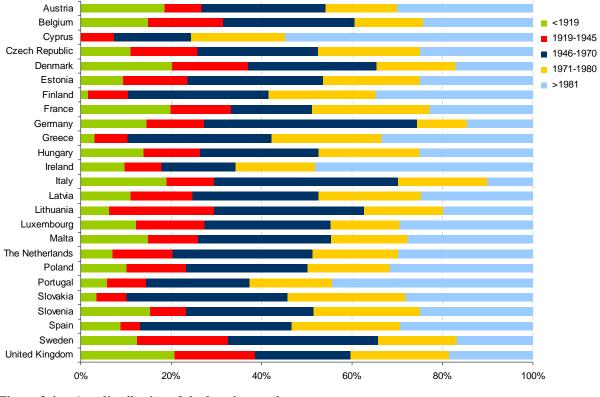

Figure 3.4 Age distribution of the housing stock Source: [BOVERKET & MMR 2005]

3.5 Derived building age and building size typology

The major groups of buildings – single-family houses, multi-family houses and high rise buildings – in each country have been grouped according to age categories. Table 3.4 provides, as an example, the information gathered for multi-family houses in France. Annex A contains the data for all countries and building groups.

 Table 3.4
 Country specific table of dwellings grouped according to age and size for multi-family houses in France

| houses | dwelling stock in% | family dwellings in % |
|-----------|----------------------|---|
| 3 451 500 | 12 | 39 |
| 4 690 500 | 16 | 53 |
| 708 000 | 2 | 8 |
| 8 850 000 | 30 | 100 |
| | 4 690 500 708 000 | 4 690 500 16 708 000 2 8 850 000 30 |

The overall grouping of the EU-25 housing stock according to size is shown in Figure 3.5. As already highlighted above, there is a different national distinction between high-rise buildings and multi-family buildings. Therefore, it would be more accurate to say that about 53% of the EU-25 building stock is composed of single-family houses while the remainder are "bigger" buildings like multi-family houses and high-rise buildings.

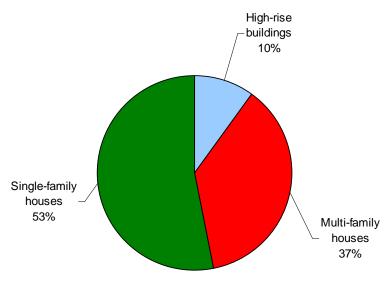

Figure 3.5 Distribution of the entire housing stock in the EU-25 Source: [EUROSTAT 2005b]

3.6 Material and building design typology

As an example, the process followed to identify the material and masses for each building type is described here. In France, for instance, multi-family houses built between 1945 and 1990 cover 16% of the entire French building stock and represent a total of 4 690 500 dwellings (see Table 3.4). An iterative process started from these preliminary building types. For each building type a typical representative building model with corresponding construction procedures and material used along with masses had to be derived.

Sometimes average building types were assumed. For example, in one country, mainly multifamily buildings with four and six storeys were found. The materials used in these two different building types were comparable, so in this case it was decided to regard these building types as a building with five storeys (average). For this approach, expert knowledge as well as a sound research in literature about typical construction in certain time periods in particular countries for specific building types have been used.

 Table 3.5
 Result from the expert poll performed within the COST C16 action (ESF-COST-C16)

28

The construction details for all climatic regions in the EU-25 collected in the EPIQR has also been used in this project [EPIQR 1996]. The EU-project INVESTIMMO [BAUER ET AL. 2004], provided relevant data on the lifespan of the used materials and the European COST action C16 detailed the actual state of theses buildings today. The literature sources for these EU-projects are given in Annex E.

Nevertheless, the data derived from these references were too rough to really build detailed construction plans for each of the major building groups. Therefore, design and construction characteristics of these building types were defined taking into account literature research and experts knowledge on typically used material for each of the considered zones.

The result is a construction description with detailed descriptions of used material and masses as shown in Table 3.6 below which is an example for a multi-family house in France.

| Multi-family house | Brick masonry, reinforced concrete flooring, pitched roof 20 $^\circ$ |
|----------------------------|---|
| Year of construction | 1945 - 1990 |
| Building type | Multi-family house |
| Dimension | 32 m x 12 m |
| Floor to floor height | 3 m |
| Roof | Pitched roof 20° |
| Roof cladding | Brick |
| External wall | Brick masonry 30 cm |
| Interior load-bearing wall | Reinforced concrete 20 cm |
| Interior wall | Plasterboard 10 cm |
| Plaster | Exterior plaster: lime-cement; interior plaster: lime-gypsum |
| Floor | Reinforced concrete 20 cm |
| Basement wall | Reinforced concrete 20 cm |
| Basement ceiling | Reinforced concrete |
| Foundation | Reinforced concrete |
| Window | Wooden frame and double-glazing |

Table 3.6Material and masses for a typical multi-family house in France (between 1945 and 1990)

The dimensions used in the example shown in Table 3.6 are a representative average for the used materials that are common for the construction in the specific country for the specific age and building type.

Further investigation of the used materials showed that this building type is also found in the following age category (after 1990) and altogether represents around 10% of the whole building stock. The remaining multi-family buildings between 1945 and 1990 were built with concrete, light concrete, limestone and also brick with insulation. These materials and their respective constructions are described in other building types and can be found in Annex B.

Not only did the different materials and structures of the façade cause the creation of additional building types for one selected national group of buildings at a certain age and size, but also the structure and materials of floors and roofs. Flat roofs and pitched roofs, for instance, with their different constructions were to be split into two groups. Concerning masses and materials, it was possible to assemble at least buildings with mansard roofs, pitched roofs and hipped roofs in one group. For floors, there are two different groups: wooden floors and massive floors of stone and/or concrete that created a different grouping.

3

3.7 Grouping building types from different countries

In general, there were sufficient data for the building types in available country level data. For some countries (e.g. Estonia), data were not available with sufficient accuracy. However, sound data could be derived from neighbouring countries with comparable climatic conditions and with comparable historic economic and political backgrounds.

When similar data were available for similar building types defined in two different countries, those were merged into one building type. This was done under the following conditions:

- comparable climatic boundary conditions
- comparable techniques and materials used for the building which is only possible, if comparable economic and political boundary conditions are found.

To ensure comparable climatic boundary conditions, the heating degree days of each country were a suitable indicator for comparison. This indicator is the best way to represent similar zones for heating in the EU-25. The long term average of the heating degree days (HDD), based on the period 1980-2004, are used. A relatively long term base period is desirable to avoid the influence of short term changes in mean temperatures. Thereby, three different categories, shown in Table 3.7, have been set.

Table 3.7 Grouping of heating degree days

Sources: [EUROSTAT 2005a, GIKAS & KEENAN 2006]

Besides heating degree days, political and economic boundary conditions were also taken into account when defining geographical zones and building types. For instance, the political system in eastern European countries until 1990, characterized by a centralized planning process which included building strategies, sometimes resulted in raw materials shortages. This is reflected in typical apartment buildings in all Eastern European countries.

By applying the transnational clustering of building types (Table 3.8), it was possible to reduce the number of building types tremendously without increasing the risk of error.

| | France | Italy | Greece | Portugal | Spain | Malta | Cyprus |

Table 3.8Transnational clustering of similar national building types (example for a single-family
house in zone 1)

3.8 Typology of residential buildings in the EU-25

The variety of special buildings, e.g. historical buildings with straw roofs would lead to a huge number of building types. Therefore, a cut-off was defined that at least 70% of the whole building stock in each country as well as in the EU-25 building stock are covered by specific building types.

The European residential buildings sector is separated into 53 typical building types. Of these 53 building types, 19 types were each subdivided into one group representing the existing building stock, and one group representing the current typical practice of residential building construction (new buildings), respectively. Thus, in total 72 building types were identified that altogether represent 80% of the whole building stock in the EU-25 in terms of residential area. The grouping according to size and to climatic region is highlighted in Table 3.9.

Table 3.9Number of building types in each zone

The building types are listed in Table 3.10. In the second column of this table, the climatic zone is given (Z1 stands for southern European countries, Z2 stands for middle European countries and Z3 stands for northern European countries). The short name for each construction is given in the third column. The notation is "Building type (XX)_Number(3 digits)" with "SI" standing for single-family houses, "MF" for multi-family houses and "HR" for high-rise buildings.

| | |

Energy balance

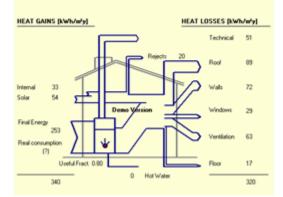

Figure 3.6 Example of a datasheet per building type In this example, "Z1_SI_001" stands for the single-family house 001 in Zone 1 (Southern European countries)

EXISTING

Each datasheet contains a list of statistical country data such as the number of dwellings that are covered by this building type in each country. A short description of the typical material, dimensions and structure, as well as the residual lifespan (in three rough estimates of 20, 30 and 40 years) is also given. The energy balance of the building from the epiqr® software is shown at the bottom of the datasheet (see Section 4.5.3.1).

A second datasheet per building type provides the detailed composition of building elements, masses, volumes and densities (see the example in Table 3.12). The complete set of datasheets for all evaluated building types can be found in Annex B.

Table 3.12 Detailed information about the building type

In this example, "Z1_SI_001" stands for the single-family house 001 in Zone 1 (Southern European countries)

4 Life cycle assessment methodology

This chapter describes the methodology, the assumptions and the data used to implement the Life Cycle Assessment (LCA) of the buildings types defined in the previous chapter.

4.1 Environmental impact categories

The life cycle impacts assessed for the different building types were aggregated in terms of several impact categories which were selected on the basis of scientific robustness, relevance and practicability. These are:

- Acidification Potential (AP)
- Eutrophication Potential (EP)
- Global Warming Potential (GWP100)
- Ozone Layer Depletion Potential (ODP)
- Photochemical Ozone Creation Potential (POCP).

The environmental indicators "Primary Energy from renewable sources" and "Primary Energy from non-renewable sources" are also quantified.

The incorporated greenhouse gases (related to the carbon content of the used renewable resources like wood) was also quantified, together with the greenhouse gas emissions resulting from fuel combustion and industry processes ('Output GWP').

Due to missing scientific robustness of the underlying methods, environmental impact categories related to human and eco-toxicity, abiotic resource depletion, as well as to land use were not addressed.

For the characterisation of the above listed environmental impacts, the CML (Centre of Environmental Science) characterisation model version 2001 was used [CML 2001].

4.2 Functional unit

The selected primary functional unit of the life cycle model is the 'use' of one square metre living area over the period of one year. To calculate life cycle impacts for this functional unit, one specific building type was analysed over its entire life span. The life span corresponds to the years of living in the building with all refurbishment actions considered and the consumption of energy for heating and cooling. This functional unit relates to all life cycle phases, i.e. construction, use phase and recycling.

These functional units permit the direct comparison of differently sized building types or of building types with different residual service lives (see Section 4.3.2 for information about the service lives of buildings).

4.3 **Product system and system boundaries**

Once the list of buildings types in their respective geographical surroundings had been prepared with their main technical aspects and influencing surrounding conditions, the system boundaries for the life cycle models were defined.

With regard to the building's layout, the life cycle model integrates six main construction elements:

- basement (including the building's foundation)
- exterior walls (including plaster & exterior paint)
- interior walls (including plaster)
- floors/ceilings
- roof
- windows.

The interior construction, fittings and finish, and heating and cooling systems (e.g. HVAC, heating systems and cooling equipment/services, mechanical ventilation systems and building automation) are not considered as they are not relevant for the identification of improvement options. The exterior area surrounding the building and the infrastructure services are also not considered.

For the sake of consistency, the general system boundary is similar for all building types to be assessed and includes all life cycle stages:

- production and transport of building materials
- refurbishment
- heating and cooling
- waste management (demolition and refurbishment).

4.3.1 Omission of processes

Some building parts, other processes and aspects are excluded from the system due to minor relevance: the operation of the construction (site), and the entrance doors.

The minor relevance of the construction operation has been justified in several studies. [LÜSNER 1996], for instance, shows (for infrastructure building projects) that the operation of construction generally does not exceed 2% (in some rare cases, the construction operation may sum up to approx. 9%) of the life cycle impacts for bridges or roads. These examples, however, include the transport of construction materials and products to the construction site. The impact of transport has been attributed to each individual building element. On this basis, and since the major environmental impacts lie in the use phase (especially heating energy uptake), the construction operation can reasonably be neglected.

Compared to the rest of the building, entrance doors have small masses and are generally made of the same materials as windows. The analysis of windows shows that they do not bear the most relevant environmental impacts within the building's life. Therefore, the minor relevance of doors can reasonably be assumed.

4.3.2 Service lives of buildings and building types

For any manufactured product, the service life or life span can be fairly accurately estimated from experience (and similar products). Conversely, the residual life span of a building is not as easy to estimate due to non-technical factors that can limit the actual building's residual service. This holds especially true for long term predictions. The profile of the building owner/occupant (social status), the building's surrounding, e.g. nearby mining or underground transportation or the occurrence of earthquakes) are two examples that can affect the residual life of the building.

The residual service life of each building is determined by both non-technical decisions and by the technical state of the building [BAUER ET AL. 2004]. For analytical purposes the maximum residual service life of a building has been established at 40 years. For some building types, the residual service life is assumed to be below 40 years, but, in no cases fewer than 20 years.

For new building types, the reference service life is generally estimated to reach or exceed 40 years. However, whenever the residual service life was estimated to be 40 or more years, the analysis of the impact of the use phase was limited to 40 years. This upper limit was established due to the uncertainties inherent to the long term and because it provides a reasonable framework in the definition of policy measures which generally do not consider long term goals beyond 2050.

Improvement options concern both existing and new building stock. Therefore, in order to perform life cycle assessments and to highlight the most environmentally relevant processes, a differentiation was made between "new buildings" (buildings assumed to be currently built and to represent state-of-the-art construction practice in Europe) and "existing buildings".

4.3.3 New buildings

The building type "new building" is defined as a new construction, where the most common current practices over the last few years until today are considered. The generic life cycle model for a new building includes three phases, the "Construction Phase", the "Use Phase" and the "End-of-Life Phase". These phases are divided into several sections, containing all relevant processes (see Figure 4.1).

The "Construction Phase" divides into "Production of Construction Materials" and "Transport of Materials". The process of construction and its related processes are not considered.

The "Use Phase" contains the relevant processes throughout the building's reference service life in particular "Refurbishment", and "Heating & Cooling", and "Refurbishment" being all actions that are required to maintain the function of the building throughout its service life, without altering the building's environmental performance. "Heating & Cooling" considers the total heating energy demand and the total cooling energy demand as average energy consumption throughout the building's reference service life. The respective mix of energy carriers is considered and specifically built up for this analysis.

The life cycle phase "End-of-Life" divides into the sections "End-of-Life Construction" and "End-of-Life Refurbishment". These sections consider the handling of the wastes which accumulate during the demolition of the original construction materials and the wastes which accumulate during the refurbishment of the building.

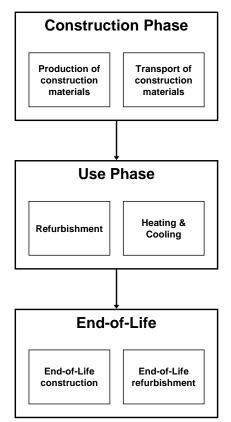

Figure 4.1 Life cycle phases and system boundaries of the life cycle model for a new building including "Construction Phase", "Use Phase" and "End-of-Life"

The life cycle inventory data use average European data, e.g. for the production of construction materials and mixes of energy carriers. Parameters like 'heating energy demand', however considers the geographical resolution of the respective building type.

4.3.4 Existing buildings

While the "new building" scenario considered the construction phase of the building, the "existing building" scenario is limited to the "Use Phase" and the "End-of-Life Phase", since the construction phase of existing buildings is not relevant for the identification of improvement options (see Figure 4.2).

The "Use Phase" and the "End-of-Life Phase" are similar to the new building scenario. The only difference is the service life time within the "Use Phase". In the new building scenario, the service life corresponds to the total time span between construction and end-of-life of the building and is referred to as the "reference service life". Within the existing building scenario, the service life represents the time span between the time of assessment ('today') and the End-of-Life of the building. This time span is referred to as the "residual service life".

The "End-of-Life" phase is divided into "End-of-Life Construction" and "End-of-Life Refurbishment". These sections consider the handling of the wastes which accumulate during the demolition of the original construction materials and the wastes which accumulate during the refurbishment of the building.

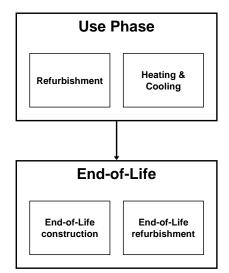

Figure 4.2 Life cycle phases and system boundaries of the life cycle model for an existing building including the "Use Phase" and "End-of-Life"

4.4 Background data

The term "background data" refers to life cycle inventories of construction materials and energy as well as of transportation processes and waste management processes.

In order to assure consistency for the life cycle models of all building types, all background data used except heating energy were from European average datasets. This means that for construction materials, the datasets represent technologies on average levels for the EU-25. These construction materials also contain European (EU-25) boundary conditions such as EU-25 datasets for electric or thermal energy or intermediate products and represent a common European market for construction materials. Using such European average datasets does not show the variability, for instance of the industry producing construction materials industry in Europe and thus has the advantage not to bias the analysis of the life cycle models by accounting for differences in different production techniques. This bias would reduce the significance of the results as the clear denotation of environmental hotspots in the structure and design of buildings would contain higher uncertainties on the origin of environmental impacts.

Based on previous research on the life cycle impacts of buildings, as well as on other LCA studies of buildings, the use phase, particularly the energy demand for heating, is the most likely phase to bear the majority of the life cycle impacts. The composition of the heating energy mix that is used within the model is not related to any constructional questions, but has a significant impact on the overall life cycle impacts of a building type. Therefore, the heating energy mix varies according to the geographical zones adopted (see Section 4.4.1).

Background datasets were taken from the GaBi 4 database as far as possible [LBP & PE 2007]. Additional datasets were modelled with the same boundary conditions and by applying the same modelling methodology as for existing datasets. Existing, as well as newly modelled background datasets are generally based on information from industry and were generally cross-checked with literature data. Where applicable, the information was used to model technology mixes for the production of the respective construction material. In order to assure the data quality of the background datasets, the background data models were validated through completeness checks, sensitivity checks and consistency checks.

4.4.1 Heating energy

The consumption of heating energy is given for every building type individually (see Annex C) and the composition of the heating energy mix is aggregated for each zone separately. [EUROSTAT 2007] provided a mix of primary energies for the total consumption of energy in households. Additionally, [KEMNA ET AL. 2006] provided a table containing the EU residential heat load assessment. By combining both tables, the country-specific mixes of energy carriers were calculated. For each zone, the energy carrier mix was calculated from the weighted energy mixes of the individual countries. The total number of dwellings, given in Annex A, serves as the weighting factor for these data (see Table 4.1). The final zone mix was calculated by multiplying the "share of zone energy" with the respective share for each energy carrier.

The heating energy mixes for each country contain heat as an energy carrier for residential building heating. The life cycle information for the provision of heat was put together on a country-wise level. Information on the composition of primary energy mixes for thermal energy from heat was taken from [IEA 2004]. An efficiency of 90% was assumed for heat as energy carrier, in order to take distribution losses into account.

| Zone and country | Solid fuels | Oil | Gas | Electri- city | Heat | Renewable energy sources | Number of households | Share of | zone |

 Table 4.1
 Heating energy carrier mix per country and weighting factors to produce zone-specific mixes

4.4.2 Cooling energy

No EU standard method to calculate the cooling energy demand for residential buildings is yet agreed upon and little information and literature is available for its calculation. [DALIN ET AL. 2006] presented a calculation method for the specific cooling demand that is based on a newly introduced European Cooling Index related to the climatic conditions throughout Europe. This specific cooling demand represents a potential energy demand that is not met today and will not necessarily be met in the future (see Table 4.2).

| Zone/ | Specific cooling | Expert judgement | Specific cooling | Weighting | Zone average |
|-------------------|-----------------------|--|-----------------------|---------------------|-------------------------------|
| Country | energy potential | on the fraction of actual consumption of the cooling | energy consumption | factor ^a | cooling energy consumption |
| | kWh/m ² *a | energy potential % | kWh/m ² *a | Mio. m ² | kWh/m ² *a |
| Zone 1 | K VV 11/111 * a | /0 | K VV II/III a | 6 232 | 0.773 |

 Table 4.2
 Specific cooling energy consumption factors per country and weighting factors for the calculation of average cooling energy factors per zone

This demand would be met, if the total living area was cooled throughout the entire cooling season. This might hold true for office buildings but not for residential buildings, where the actual cooling energy demand per living surface unit is likely to be lower because a smaller fraction of the building area is cooled. In addition, the cooling devices are switched on during shorter periods. Cooling demand is also lower in residential buildings than in office buildings as a result of more natural ventilation (e.g. opening the windows during the night).

Based on the calculated cooling energy potential according to [DALIN ET AL. 2006], expert judgement that give the actual used fraction of the theoretical potential are made. These expert judgements are made in each country. Using the total considered building stock per country in million m² as the weighting factor, zone-wide average values are calculated from these country-specific values (see Table 4.2).

The figures obtained were cross-checked with [ADNOT ET AL. 2003] who give information on the total cooling energy demand. They focus on the total cooled areas (residential and non-residential buildings). According to that study, the residential area amounted to 5.75% of the total cooled area within the EU-15 in 2005. Based on that project, the specific cooling energy consumption for that zone (Table 4.3) was derived assuming that:

- the European average share of 5.75% cooled area in the residential sector has a sufficiently low deviation and may be used to express this ratio in every considered country
- the consumption of cooling energy per cooled area is constant throughout all countries and all sectors.

One can derive that in the countries from zone 1 (except for France), the cooling energy consumption from [ADNOT ET AL. 2003] is lower than the expert estimation. For zone 2 and zone 3, the values from [ADNOT ET AL. 2003] are higher than the expert estimation based on [DALIN ET AL. 2006] for all countries.

The deviations can be explained as for the calculations according to [ADNOT ET AL. 2003], a European average of 5.75% for the share of cooled residential areas and a constant cooling energy demand per cooled area was assumed. Thus, the value in southern European countries with greater cooling load should be higher. Accordingly, the values for the middle and northern countries should be lower. Nevertheless, the comparison of the conclusions drawn from the expert judgment based on [DALIN ET AL. 2006] with the values derived from [ADNOT ET AL. 2003] show good consistency, namely respectively 4 490 GWh/a and 4 818 GWh/a cooling demand for the EU-15 (7% gap).

| Zone/Country | Cooling energy demand for all sectors in 2005 [ADNOT ET AL. 2003] | Cooling energy demand for residential buildings in 2005 ^a | Total residential area | Calculated specific cooling energy demand | Specific cooling energy consumption (see Table 4.2) |

4.4.3 Life cycle inventories of construction materials

On the basis of the detailed technical descriptions of all building types (see Annex B), life cycle inventories (background datasets) for the required construction materials were created. Table 4.4 shows the full list of construction materials that were for the life cycle models of all building types.

The comprehensive list of construction materials used for each building type and the corresponding relevant technical parameters is given in Annex B. This table was revised for the modelling of the building type life cycle models. For all construction materials, two parameters that are required for the modelling were added:

- residual, respective reference service life of the entire building type, and of each construction material, specific to the respective building type and the respective construction element
- refurbishment factors.

These factors yield the number of refurbishment actions for each construction element over the building type's residual service life.

Besides these added parameters, the material densities given in this table were revised and matched to densities as given in GaBi 4 databases [LBP & PE 2007].

| Construction material | Comment |
|--------------------------------------|---|
| Aerated concrete element | Density 0.6 reinforced |
| Clay | |
| Clinker | |
| Concrete | C20/25 |
| Concrete roof tiles | |
| Exterior plaster | Lime-cement scratch plaster |
| Façade paint | Mix of previous coat and emulsion paint, synthetic resin and silicate |
| Gravel | Grain size 2/32 |
| Gypsum board | |
| Insulation materials mix | Containing: (default mass shares in brackets) ^a |
| | - Stone wool (36%) |
| | - Glass wool (24%) |
| | - Expanded Polystyrene EPS (28%) |
| | Polyurethane PUR (7%)Extruded Polystyrene XPS (5%) |
| Interior plaster | Lime-gypsum |
| Light-weight concrete | Pumice hollow block (density 0.8) |
| Light-weight concrete | Expanded clay block (density 0.6) |
| Limestone (CaCO ₃) | Expanded elay block (density 0.0) |
| Oriented Strand Board (OSB) | OSB III (water content 8%) |
| Ready-mix concrete | C 20/25 |
| Reinforced concrete | Mass of reinforcement wire may be adjusted (default: 160 kg/m ³) |
| Roof tiles | Mass of reinforcement whe may be adjusted (default. 100 kg/m) |
| Rubble stone masonry | Density 1.6 |
| Sand | Grain size 0/2 |
| Sand-lime brick | Orani size 0/2 |
| Screed | Ambridgeta |
| Screed | Anhydrite Cement |
| | |
| Timber spruce | Absolute dry |
| Vertically perforated brick | D5 (matrix 0.50/) |
| Wood fibre board | P5 (water content 8.5%) |
| Wood paint | Inclusive application |
| a) Mass shares are estimations, base | a on [2005] and [MENDEZ nd]. |

 Table 4.4
 Construction materials included in the life cycle models

4.5 Generic building models description

The approach of generic models adopted to model selected types of buildings is applied to manage complex product models and it gives the opportunity to provide transparent and summarized results. This is realized by forming flexible models with parameter variations, including previously modelled materials and parts. The parameter variation offers the possibility to adapt the models to specific product properties or modelling design scenarios without the need of forming entirely new models.

Generic models were used for the analysis of the complete manufacturing of a product. By variation of significant parameters, each single module of the product chain could be varied. By implementing the entire manufacturing process into a modelled life cycle, all the effects of each life cycle phase could be recognized depending on the different variations.

The modelling of the selected types of buildings within their various geographical settings imposed challenges is comparability, in modelling efficiency and in clarity of the results. In order to achieve sound, consistent and transparent results through efficient modelling of the selected building types, generic building models with a focus on the building structure were set up, so the three generic building models represent the groups: single-family buildings, multi-family buildings and high-rise buildings.

These generic models were then adapted to varying building types and different geographical settings by parameterizing key variables such as mass or energy fluxes. The generic models also provided the basis for the assessment of different building materials such as concrete, wood, bricks, etc. In order to identify all relevant effects of using specific building materials and constructional elements, all relevant processes, raw materials and operation processes were included in the models.

The generic models were built up within the LCA software system GaBi 4 [LBP & PE 2007]. This comprises a consistent and extensive up-to-date database of processes and materials used in the building industry and in the use phase of the buildings. Regional differences are taken into account in the building's use phase in terms of zone specific heating energy mixes and zone-specific potential cooling energy demand factors. All used material, auxiliary materials and energy datasets are modelled within European boundary conditions.

4.5.1 Modelling of the selected building types in their geographical resolution

The generic life cycle models for new and existing buildings for each group of residential dwellings were used as the basis for the preparation for the new life cycle models of individual building types. Each building type within the three groups of residential dwellings was modelled within its respective geographical areas. This yielded 72 life cycle models for a variety of building types, each modelled within its respective geographical area. The data sets used for materials and energies were taken from the GaBi 4 software and represented respective European system boundaries for the specific energy mixes for the three different geographical regions [LBP & PE 2007].

The generic life cycle models included the three life cycle phases of each building type: the Construction Phase, Use Phase, and End-of-Life.

All life cycle models share a common building structure, consisting of six construction elements or assemblies thereof (see Figure 4.3). These construction elements included the roof, exterior walls, interior walls, windows & entrance doors, floors & ceilings and the basement & foundations.

The construction elements contained all relevant assemblies, sub-assemblies, construction materials and processes required to model the respective building types within their geographic area in a representative way. This included, e.g. for the roof, the roof truss, roofing tiles, vapour barrier and the roof insulation. Consequently, the level of detail and the processes and materials included may vary between different construction materials, depending on the relevance of the individual process or material.

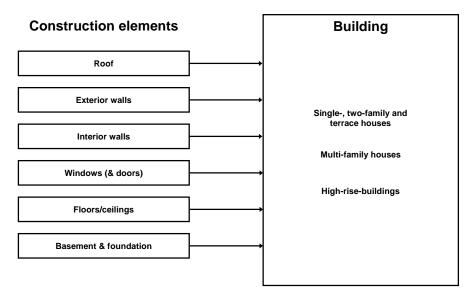

Figure 4.3 Common building structures,, including all relevant and considered construction elements, for all building types within all groups of residential dwellings

This common structure was used to assess improvement potentials by improving the environmental performance of individual construction elements by applying specific refurbishment measures.

In the following sections, the modelling of the different construction elements for the "Construction Phase" is described (Section 4.5.2). The modelling of the "Use Phase" (Section 4.5.3) and the "End-of-Life Phase" (Section 4.5.4) is also explained in the next sections.

The validation of the models in terms of their calculation routines, and their outcome was done with completeness checks, sensitivity checks and consistency checks to ensure the validity of the life cycle inventories.

All relevant processes were considered and modelled to represent the specific model as far as possible. Background processes were taken from the publicly available professional GaBi 4 databases [LBP & PE 2007] as far as was available. New data sets were also modelled, using the same system boundaries and levels of detail as existing data sets. The data sets use European boundary conditions. To ensure consistency, individual data, foreground data and background data were modelled tp the same degree and quality level as applied by [LBP & PE 2007].

For the later analysis of the different building type models, it was necessary to group the used construction materials. By this grouping, a detailed analysis of the environmental impacts of the construction materials was possible. Table 4.5 gives an overview of all used construction materials and their respective grouping. This grouping was one of the bases of for the impact assessment.

| Table 4.5 Grouping list for the construction materials | |
|--|------------------------------|
| Process | Grouping |
| Aerated concrete element (density 0.6 reinforced) | Concrete |
| Concrete C20/25 | Concrete |
| Concrete roof tile | Concrete |
| Ready mix concrete C20/25 | Concrete |
| Clinker | Stones |
| Light weight concrete (pumice) hollow block (density 0.8) | Stones |
| Light weight concrete (expanded clay) block (density 0.6) | Stones |
| Limestone (CaCO ₃) | Stones |
| Rubble stone masonry (density 1.6) | Stones |
| Sand – lime brick | Stones |
| Vertically perforated brick | Stones |
| Clay | Other materials |
| Exterior plaster (lime cement scratch plaster) | Other minerals |
| Glass wool (core insulation board) | Other minerals |
| Gravel (grain size 2/32) | Other minerals |
| Gypsum board | Other minerals |
| Interior plaster (lime gypsum) | Other minerals |
| Roof tile | Other minerals |
| Sand (grain size 0/2) | Other minerals |
| Screed (anhydride) | Other minerals |
| Screed (cement) | Other minerals |
| Stone wool (flat roof insulation board, 180) | Other minerals |
| Reinforced steel (wire) | Steel |
| EPS manufacturing (expanded polystyrene foam, PS 20) | Foam plastics |
| Polyurethane rigid foam (PU) | Foam plastics |
| XPS manufacturing (extruded polystyrene foam) | Foam plastics |
| Bitumen at refinery | Non foamed plastics |
| Oriented strand board (OSB) III | Wood |
| Timber spruce abs. dry | Wood |
| Wood fibre board (P5) | Wood |
| Wood-aluminium window (0.8 x 1.2) with single glazing | Wood-aluminium window |
| Wood-aluminium window (1.0 x 1.5) with single glazing | Wood-aluminium window |
| Wood-aluminium window (1.0 x 2.1) with single glazing | Wood-aluminium window |
| Wooden window $(0.8 \text{ x } 1.2)$ with single glazing | Wooden window |
| Wooden window $(1.0 \text{ x } 1.5)$ with double glazing | Wooden window |
| Wooden window $(1.0 \text{ x } 1.5)$ with single glazing | Wooden window |
| Wooden window $(1.0 \text{ x } 2.1)$ with single glazing | Wooden window |
| Plastic (PVC) window (1.0 x 1.5) with double glazing | PVC window |
| Plastic (PVC) window (1.0 x 1.5) with single glazing | PVC window |
| Plastic (PVC) window (1.0 x 1.5) with triple glazing | PVC window |
| Emulsion paint (synthetic resin) | Coating and sealing material |
| Wood paint inclusive application | Coating and sealing material |
| | |

 Table 4.5
 Grouping list for the construction materials

4.5.2 Modelling of the Construction Phase

The modelling of the parameterised generic module of a building is explained by using a single-family house (building type $Z1_SI_001$) as an example. All parameter settings are adapted to the specifics of this building type.

In the generic module, parameters are used to change the thickness and area (roof, floors and walls); number of pieces (windows) for each material. Fixed or calculated parameters are used to calculate the mass as well as to define the density of the respective material.

The construction phase is split into the modelling of the different construction elements. All construction element modules use a transport model. This transport model is necessary to build up the specific diesel consumption of the transport of the respective construction elements. The diesel consumption depends upon the weight of the transport cargo and the transport distance. The transport distance was estimated by a distribution model which was based on two parameters: the population density of Germany and the distance. For the calculation, the defined Nielsen-urban centres were taken into account. According to the average population density – distance relation, the resulting transport distance was 293 km (for detailed information on the method see [BAITZ 1995]).

4.5.2.1 Roof

Table 4.6 shows the list of parameters which can be selected to model the construction element roof. The variable material parameters are divided in two groups. For each material, the thickness and the area can be chosen to represent a specific roof for the selected building type.

In this specific case, the roof is represented by the following materials: wooden joist (timber spruce 12%), roof battening (timber spruce 12%), an insulation mix, reinforced concrete and exterior plaster. The materials insulation mix and reinforced concrete are also parameterised. The share of the different insulation materials can be specified for each construction element. In this example the insulation mix consists of 28% EPS material, 24% glass wool material, 7% PUR material, 5% XPS material and 36% stone wool material. The share of steel material in the reinforced concrete is 6.7%.

By changing the material parameters of the roof, the total weight of the construction element is adjusted accordingly.

| Parameter | Value | Unit | Parameter description |
|-----------------|-------|----------------|--|
| Mat1_area | 21.88 | m ² | Area of wooden joist (timber spruce 12%), distance 0.6mx0.1 |
| Mat1_thickness | 0.16 | m | Thickness of wooden joist (timber spruce 12%), distance 0.6mx0.1 |
| Mat2_area | 12.5 | m ² | Area of roof battening (timber spruce 12%) |
| Mat2_thickness | 0.04 | m | Thickness of roof battening (timber spruce 12%) |
| Mat3_area | 120 | m ² | Area of roof tile |
| Mat3_thickness | 0.02 | m | Thickness of roof tile |
| Mat4_area | 0 | m ² | Area of wooden boarding |
| Mat4_thickness | 0 | m | Thickness of wooden boarding |
| Mat5_area | 0 | m ² | Area of stone panel |
| Mat5_thickness | 0 | m | Thickness of stone panel |
| Mat6_area | 0 | m ² | Area of bitumen |
| Mat6_thickness | 0 | m | Thickness of bitumen |
| Mat7_area | 0 | m ² | Area of reinforced concrete |
| Mat7_thickness | 0 | m | Thickness of reinforced concrete |
| Mat8_area | 0 | m ² | Area of interior plaster (lime-gypsum) |
| Mat8_thickness | 0 | m | Thickness of interior plaster (lime-gypsum) |
| Mat9_area | 0 | m ² | Area of gravel |
| Mat9_thickness | 0 | m | Thickness of gravel |
| Mat10_area | 0 | m ² | Area of insulation |
| Mat10_thickness | 0 | m | Thickness of insulation |
| Mat11_area | 0 | m ² | Area of mineral insulation |
| Mat11_thickness | 0 | m | Thickness of mineral insulation |
| Mat12_area | 0 | m ² | Area of prefabricated concrete joist |
| Mat12_thickness | 0 | m | Thickness of prefabricated concrete joist |
| Mat13_area | 0 | m ² | Area of concrete tile |
| Mat13_thickness | 0 | m | Thickness of concrete tile |
| Mat14_area | 0 | m ² | Area of exterior plaster (lime-cement) |
| Mat14_thickness | 0 | m | Thickness of interior plaster (lime-gypsum) |
| EPS | 0.28 | - | Share (mass) of EPS insulation |
| XPS | 0.05 | - | Share (mass) of XPS insulation |
| Glaswolle | 0.24 | - | Share (mass) of glass wool insulation |
| PUR | 0.07 | - | Share (mass) of PUR insulation |
| Stonewool | 0.36 | - | Share (mass) of stone wool insulation |
| Anteil_stahl | 160 | kg/m³ | Share reinforcement steel (kg steel/m ³ concrete) |
| M3_stahlb | 2 400 | kg/m³ | Density reinforced concrete, including Reinforcement |

 Table 4.6
 Parameter list for the roof parameter settings

4.5.2.2 Windows

Table 4.7 shows the list of parameters which can be selected to model the construction element window. In this parameter list the type and the number of windows which should be used in the building type can be selected. These are differentiated in three window types:

- wooden frame
- wood-aluminium frame
- wlastic frame.

It is also possible to choose between single-, double- or triple-glazing. The parameter selection of triple-glazing windows is important for the refurbishment actions in the use phase. In this specific case the construction element window is represented by the window type wooden frame single-glazing (1 m x 1.5 m).

| Parameter | Value | Unit | Parameter description |
|-----------|-------|-------|---|
| Window1 | 0 | piece | Window wooden frame 0.8 m x 1.2 m (with single-glazing) |
| Window2 | 22 | piece | Window wooden frame 1 m x 1.5 m (with single-glazing) |
| Window3 | 0 | piece | Window wooden frame 1 m x 2.1 m (with single-glazing) |
| Window4 | 0 | piece | Window wood-aluminium frame 0.8 m x 1.2 m (with single-glazing) |
| Window5 | 0 | piece | Window wood-aluminium frame 1 m x 1.5 m (with single-glazing) |
| Window6 | 0 | piece | Window wood-aluminium frame 1 m x 2.1 m (with single-glazing) |
| Window7 | 0 | piece | Window plastic frame 1 m x 1.5 m (with single-glazing) |
| Window8 | 0 | piece | Window plastic frame 1 m x 1.5 m (with double-glazing) |
| Window9 | 0 | piece | Window plastic frame 1 m x 1.5 m (with triple-glazing) |
| Window10 | 0 | piece | Window wooden frame 1 m x 1.5 m (with double-glazing) |
| Window11 | 0 | piece | Window wood-aluminium frame 0.8 m x 1.2 m (with triple-glazing) |
| Window12 | 0 | piece | Window wood-aluminium frame 1 m x 1.5 m (with triple-glazing) |
| Window13 | 0 | piece | Window wood-aluminium frame 1 m x 2.1 m (with triple-glazing) |
| Window14 | 0 | piece | Window wooden frame 0.8 m x 1.2 m (with triple-glazing) |
| Window15 | 0 | piece | Window wooden frame 1 m x 1.5 m (with triple-glazing) |
| Window16 | 0 | piece | Window wooden frame 1 m x 2.1 m (with triple-glazing) |

 Table 4.7
 Parameter list for the window parameter settings

4.5.2.3 Floors and ceilings

Table 4.8 shows the list of parameters which can be selected to model the construction element floors and ceiling. The variable material parameters are divided in two groups. For each material, the thickness and the area can be chosen to represent specific floors for the selected building type. Also the number of floors for the considered building type can be changed.

In this specific case the floor is represented by the material: floor timber spruce, wooden joist (timber spruce 12%), wooden boarding, interior plaster (lime-gypsum), insulation mix and reinforced concrete. The materials insulation mix and reinforced concrete are also parameterised. The share of the different insulation materials can be specified for each construction element. In this example the insulation mix consists of 28% EPS material, 24% glass wool material, 7% PUR material, 5% XPS material and 36% stone wool material. The share of steel material in the reinforced concrete is 6.7%. The number of floors is given as two.

By changing the material parameters and the number of floors and ceilings, the total weight of this construction element were automatically calculated.

4

| Parameter | Value | Unit | Parameter description | |
|-----------------|-------|----------------|---|--|
| Floor_number | 2 | pieces | Number of floors | |
| Mat1_area | 90 | m^2 | Area of floor timber spruce | |
| Mat1_thickness | 0.03 | m | Thickness of floor timber spruce | |
| Mat10_area | 0 | m^2 | Area of anhydrite screed | |
| Mat10_thickness | 0 | m | Thickness of anhydrite screed | |
| Mat11_area | 0 | m^2 | Area of breeze concrete block | |
| Mat11_thickness | 0 | m | Thickness of breeze concrete block | |
| Mat2_area | 15.63 | m^2 | Area of wooden joist (timber spruce 12%), distance 0.6 m x 0.1 m | |
| Mat2_thickness | 0.16 | m | Thickness of wooden joist (timber spruce 12%), distance 0.6 m x 0.1 m | |
| Mat3_area | 90 | m^2 | Area of wooden boarding | |
| Mat3_thickness | 0.02 | m | Thickness of wooden boarding | |
| Mat4_area | 90 | m ² | Area of interior plaster (lime-gypsum) | |
| Mat4_thickness | 0.02 | m | Thickness of interior plaster (lime-gypsum) | |
| Mat5_area | 0 | m^2 | Area of cement floor, screed topping | |
| Mat5_thickness | 0 | m | Thickness of cement floor, screed topping | |
| Mat6_area | 0 | m^2 | Area of reinforced concrete filling | |
| Mat6_thickness | 0 | m | Thickness of reinforced concrete filling | |
| Mat7_area | 0 | m^2 | Area of ceramic block | |
| Mat7_thickness | 0 | m | Thickness of ceramic block | |
| Mat8_area | 0 | m^2 | Area of interior plaster (lime-gypsum) | |
| Mat8_thickness | 0 | m | Thickness of interior plaster (lime-gypsum) | |
| Mat9_area | 0 | m^2 | Area of insulation | |
| Mat9_thickness | 0 | m | Thickness of insulation | |
| EPS | 0.28 | | Share (mass) of EPS insulation | |
| XPS | 0.05 | - | Share (mass) of XPS insulation | |
| Glaswolle | 0.24 | | Share (mass) of glass wool insulation | |
| PUR | 0.07 | | Share (mass) of PUR insulation | |
| Steinwolle | 0.36 | | Share (mass) of stone wool insulation | |
| Anteil_stahl | 160 | kg/m³ | Share reinforcement steel (kg steel/m ³ concrete) | |
| M3_stahlb | 2 400 | kg/m³ | Density reinforced concrete, including reinforcement | |

 Table 4.8
 Parameter list for the floors/ceilings parameter settings

4.5.2.4 Interior walls

Table 4.9 and Table 4.10 show the list of parameters which can be selected to model the construction element inner walls. This construction element is split up into interior load-bearing walls and interior walls.

For each of these elements material parameters are listed. Some materials are used for both elements and some materials are specified for one of the two. For both elements it can be stated that the variable material parameters are divided into two groups. For each material the thickness and the area can be chosen to represent a specific roof for the selected building type.

In this specific case the complete construction element inner walls is represented by the materials: interior plaster (lime-gypsum), wooden construction, reinforced concrete and solid brick. The material reinforced concrete is also parameterised. The share of steel material in the reinforced concrete is 6.7%. By changing the material parameters of the inner wall elements, the total weight of the construction element inner wall will automatically be calculated.

| Parameter | Value | Unit | Parameter description |
|----------------|-------|----------------|--|
| Mat1_area | 100 | m ² | Area of interior plaster (lime-gypsum) with straw |
| Mat1_thickness | 0.04 | m | Thickness of interior plaster (lime-gypsum) with straw |
| Mat2_area | 100 | m^2 | Area of wooden construction |
| Mat2_thickness | 0.08 | m | Thickness of wooden construction |
| Mat3_area | 0 | m^2 | Area of plaster board (gypsum) |
| Mat3_thickness | 0 | m | Thickness of plaster board (gypsum) |
| Mat4_area | 0 | m^2 | Area of reinforced concrete |
| Mat4_thickness | 0 | m | Thickness of reinforced concrete |
| Mat5_area | 0 | m^2 | Area of solid brick |
| Mat5_thickness | 0 | m | Thickness of solid brick |
| Anteil_stahl | 160 | kg/m³ | Share reinforcement steel (kg steel/m ³ concrete) |
| M3_stahlb | 2 400 | kg/m³ | Density reinforced concrete, incl. reinforcement |

4.5.2.5 Exterior walls

Table 4.11 shows the list of parameters which can be selected to model the construction element exterior walls. The variable material parameters are divided into two groups. For each material the thickness and the area can be chosen to represent specific exterior walls for the selected building type.

In this specific case the exterior walls are represented by the materials: insulation mix, reinforced concrete, exterior plaster (lime-cement), solid brick and interior plaster (lime-gypsum). The materials insulation mix and reinforced concrete are also parameterised. The share of the different insulation materials can be specified for each construction element. In this example the insulation mix consists of 28% EPS material, 24% glass wool material, 7% PUR material, 5% XPS material and 36% stone wool material. The share of steel material in the reinforced concrete is 6.7%.

By changing the material parameters of the walls the total weight of the construction element exterior walls will automatically be calculated.

| Parameter | Value | Unit | Parameter description | |
|-----------------|-------|----------------|--|--|
| EPS | 0.28 | - | Share (mass) of EPS insulation | |
| XPS | 0.05 | - | Share (mass) of XPS insulation | |
| Glaswolle | 0.24 | - | Share (mass) of glass wool insulation | |
| PUR | 0.07 | - | Share (mass) of PUR insulation | |
| Steinwolle | 0.36 | - | Share (mass) of stone wool insulation | |
| Anteil_stahl | 160 | kg/m³ | Share reinforcement steel (kg steel/m ³ concrete) | |
| M3_stahlb | 2 400 | kg/m³ | Density reinforced concrete, incl. reinforcement | |
| Mat1_area | 220 | m ² | Area of exterior plaster (lime-cement) | |
| Mat1_thickness | 0.02 | m | Thickness of exterior plaster (lime-cement) | |
| Mat10_area | 0 | m ² | Area of wooden construction | |
| Mat10_thickness | 0 | m | Thickness of wooden construction | |
| Mat11_area | 0 | m ² | Area of breeze concrete | |
| Mat11_thickness | 0 | m | Thickness of breeze concrete | |

| Mat9_thickness | 0 | m | Thickness of reinforced concrete |

4.5.2.6 Basement and foundation

Table 4.12 to Table 4.15 show the list of parameters which can be selected to model the construction element basement and foundation. These construction elements are split up into four elements:

- basement ceiling
- basement ground floor
- basement wall
- foundation.

For each of these elements material parameters are listed. Some materials are used for all elements and some materials are specified for one of the four.

For all elements it can be stated that the variable material parameters are divided into two groups. For each material, the thickness and the area can be chosen to represent a specific basement for the selected building type.

| Parameter | Value | Unit | Parameter description |
|----------------|-------|-------|--|
| Mat1_area | 120 | m^2 | Area of vaulted brick ceiling |
| Mat1_thickness | 0.07 | m | Thickness of vaulted brick ceiling |
| Mat2_area | 31.25 | m^2 | Area of wooden construction |
| Mat2_thickness | 0.08 | m | Thickness of wooden construction |
| Mat3_area | 90 | m^2 | Area of filling sand and grit |
| Mat3_thickness | 0.08 | m | Thickness of filling sand and grit |
| Mat4_area | 90 | m^2 | Area of wooden boarding |
| Mat4_thickness | 0.02 | m | Thickness of wooden boarding |
| Mat5_area | 0 | m^2 | Area of anhydrite screed |
| Mat5_thickness | 0 | m | Thickness of anhydrite screed |
| Mat6_area | 0 | m^2 | Area of insulation |
| Mat6_thickness | 0 | m | Thickness of insulation |
| Mat7_area | 0 | m^2 | Area of reinforced concrete |
| Mat7_thickness | 0 | m | Thickness of reinforced concrete |
| Anteil_stahl | 160 | kg/m³ | Share reinforcement steel (kg steel/m ³ concrete) |
| M3_stahlb | 2 400 | kg/m³ | Density reinforced concrete, incl. reinforcement |

 Table 4.12
 Parameter list for the basement and foundation parameters settings (basement ceiling)

In this specific case, the complete construction element basement and foundation is represented by the materials: vaulted brick ceiling, wooden construction, filling sand and grit, wooden boarding, reinforced concrete, brick and solid brick. The material reinforced concrete is also parameterised. The share of steel material in the reinforced concrete is 6.7%.

By changing the material parameters, the total weight of the construction element was automatically calculated.

| Parameter | Value | Unit | Parameter description | |
|----------------|-------|----------------|---------------------------|--|
| Mat1_area | 90 | m ² | Area of brick | |
| Mat1_thickness | 0.1 | m | Thickness of brick | |
| Mat2_area | 0 | m ² | Area of compact loam | |
| Mat2_thickness | 0 | m | Thickness of compact loam | |
| Mat3_area | 0 | m ² | Area of concrete | |
| Mat3_thickness | 0 | m | Thickness of concrete | |

 Table 4.13

| Mat4_thickness | 0 | m | Thickness of rubble stone masonry |

4.5.3 Modelling of the Use Phase

The modelling of the use phase of the considered building type is divided into two models. One model represents the overall heat losses (allocated to the construction elements) and the overall potential cooling energy demand over the complete considered life span of the building and the other model represents the masses of the construction elements which are exchanged during the considered life span of the building (refurbishment actions), including maintenance actions. The information on the heat losses are derived from the epiqr® software [EPIQR 1996]. The information on the cooling of residential buildings is calculated as detailed in Section 4.4.2. For each geographical region (Z1, Z2 and Z3) one specific average value is calculated and represented by a European power grid mix.

The maximum service life considered for all building types is 40 years. The life span of the building has an influence on refurbishment and maintenance actions. All actions refer to the residual service life which means that the amount of actions is calculated by this life span.

All construction materials of the construction element floor were assumed to be replaced and renewed after 20 years. Considering a life span of 40 years, the resulting refurbishment factor derived is one, meaning that the construction element have to be replaced once over the complete life span.

For all construction materials for the respective construction elements these refurbishment factors are calculated and used in the model. For detailed information see Section 4.5.3.3.

4.5.3.1 Heating

Calculating the heat losses of a building over its service life is done for each specific building type by using variable parameters. By changing these parameters, the specific heat loss for each construction element can be analysed. The required information for these parameters is:

- area (m²) per building type. For this calculation, the heating area is assumed to equal the living area as given in Annex C. Minor deviations (due to, e.g. balconies) are neglected
- aeat loss in kWh per m² and year, per construction element, respectively building aspect (such as technical heat losses or rejects) in the current situation.

The software programme epiqr® was used to calculate the energy demand, applying a calculation method based on the one specified by the European standard EN 832 [EN 832:2003]. The methodology is based on a stationary approach with monthly temperature and radiation values. Non-stationary effects of heat flux and heat storage are regarded through a multi-zone approach as well as the thermal mass of the building by taking into account all interior masses (interior walls and floors). Compared to the European standard method, the following simplifications are made:

- the construction elements are predefined in a linked pan-European database which means that the user can select appropriate constructions from a database instead of calculating the U-values manually for all building components
- the thermal mass can be calculated according to the Swiss standard by accepting 4 different construction cases:
 - extra-light (e.g. wooden constructions);
 - medium light (e.g. concrete slabs, light concrete walls and wooden flooring);
 - medium heavy (e.g. brick walls with wooden flooring);
 - extra-heavy (e.g. concrete walls and floors)
- the calculation of the ventilation losses is based on proposed losses in 1/h, ranging from 0.3 1/h up to 1.5 1/h, thus covering realistic air changes in existing buildings in Europe (though in some European countries the minimum air change rate is limited to 0.5 1/h because of hygienic reasons).

The simplifications help to drastically reduce the necessary time for assessment and calculation while also slightly reducing the accuracy. Test evaluations performed through the EPIQR project showed a maximum possible error of $\pm 10\%$ compared to standard method EN 832 [EN 832:2003].

One example of derived results with epiqr® results is given in Figure 4.4.

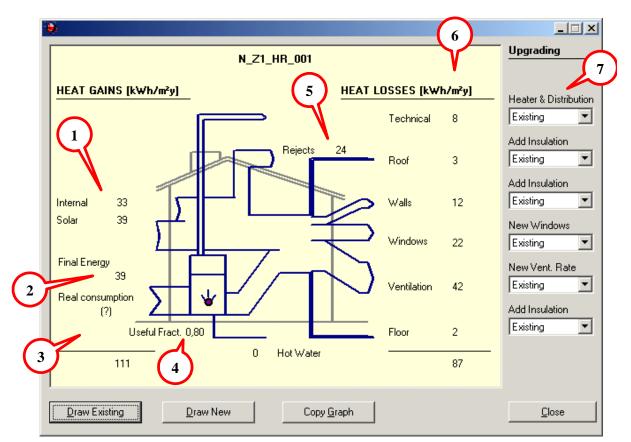

Figure 4.4 Screenshot of the software epiqr® showing as an example the results of the energy calculation

The results in Figure 4.4 are explained as follows:

- 1 Gains or energy that is available: internal gains from electrical equipment and from human beings and solar gains.
- 2 The final energy is the estimated energy consumption for space heating (note that hot water is not regarded in the calculation).
- 3 When available, this value shows the real consumption (derived from fuel consumption monitoring, e.g. in litres of fuel per year).
- 4 The useful fraction is the yield of the heating and distribution systems.
- 5 The rejects are the part of the energy that is produced by the heating system but is lost through pipe work and distribution to places where the energy is not needed.
- 6 The heat losses are the losses through the heating system, through opaque and transparent parts of the building envelope and through ventilation.
- 7 The user of the software can check the impact of an improvement measure of each or a combination of the losses. The improvements are related to the efficiency of the heat

production. "Roof", "walls" and "floor" refer to the heat losses through the respective opaque parts of the building envelope. "Windows" refer to the heat losses through transparent parts and "ventilation" corresponds to the losses resulting from gaps in the envelope (e.g. window frames).

The thickness of the arrows represents the energy losses. The thicker the graph, the higher are the losses. From Figure 4.4 it can be seen that the ventilation losses are the highest, followed by the losses through the windows.

The different heat losses through the different building elements as shown in Figure 4.4 were calculated for each building. These values are provided with the energy balance in Annex C. The overall heat losses of the respective building types over their entire service lives are also taken into account any refurbishment – and possible energy retrofitting action over the residual life of the buildings. For this purpose, three additional key parameters are defined for each building:

- reference or residual service life in years for a new and existing building respectively
- years without reduced heat loss per construction element
- reducing factor for heat loss per construction element as a result of the refurbishment measure assumed to be implemented during the building element residual life.

The two last parameters 'years with reduced heat loss per construction element' and 'reduced heat loss over the residual service life per construction element' allow efficiency gains due to refurbishment actions to be incorporated in a variable way. The effect of improvement options, having an influence on the heating of the building, can be calculated accordingly. As an example, the variable parameter settings are listed for the building type Z1_SI_001 in Table 4.16.

| Parameter name | Construction element | Parameter Value |
|---|-----------------------------|-----------------|
| Heat loss per m ² per year (kWh/m ²) | Roof | 89 |
| | Walls | 72 |
| | Windows | 29 |
| | Basement | 17 |
| | Ventilation | 63 |
| | Rejects | 19 |
| | Technical | 51 |
| Reducing factor for heat loss (%) | Roof | 93 |
| | Walls | 0 |
| | Windows | 55 |
| | Basement | 0 |
| | Ventilation | 0 |
| | Rejects | 0 |
| | Technical | 0 |
| Time without reduced heat loss (years) | Roof | 25 |
| | Walls | 40 |
| | Windows | 10 |
| | Basement | 40 |
| | Ventilation | 40 |
| | Rejects | 40 |
| | Technical | 40 |
| Area per building type (m2) | - | 150 |
| Reference service life (years) | - | 40 |

 Table 4.16
 Parameter settings for heat loss (building type Z1_SI_001)

4.5.3.2 Cooling

Section 4.4.2 described the approach necessary to derive the zone-dependent average cooling energy demand. These values are independent of the building type, thus ignoring factors such as shading or orientation of the building, which are known to have significant impacts on the cooling energy demand.

For the evaluation of the life cycle impacts from the cooling energy, the use of one cooling factor for the entire building and the fact that no allocation onto construction elements could be made, should be considered when comparing these results with allocated results for heating energy (see Section 4.5.3.1).

4.5.3.3 Refurbishment

The second model of the Use Phase represents the materials which are used during the life span of the respective building type. The life cycle models of the refurbishment of construction elements are identical to those models of the construction phase. Only the parameter settings have been varied to analyse the refurbishment actions.

The residual service life of the construction elements depend on the type of used materials they are composed of. This is captured through the so-called "refurbishment factor" which details on how often the construction materials have to be replaced. If the residual service life of a construction material is specified by 20 years, then the refurbishment factor is calculated as one (reference service life of the building minus 20 years divided by 20 years again).

The refurbishment factor is calculated individually for each construction material per building type (see Annex B).

4.5.4 Modelling of the End-of-Life

The life cycle phase "End-of-Life" divides into the sections "End-of-Life Construction" and "End-of-Life Refurbishment". Those sections consider the handling of the wastes which accumulate during demolition of the original construction materials and of the wastes which accumulate during the refurbishment of the building.

For both the EOL phases related to the construction and to the refurbishment of the building type respectively, the mass weight of the used construction materials is automatically calculated in the GaBi 4 software [LBP & PE 2007]. Therefore, for each considered building type, the respective amount of materials can be specified in the End-of-Life phase.

The construction materials are grouped in the same construction elements as for the construction phase. Five groupings are thus defined for the End-of-Life phase (roof, exterior walls, interior walls, floors, basement, and windows).

According to these groups, material composition and the masses, the environmental burdens and credits are calculated assuming corresponding waste treatment plans including recycling and energy recovery (see Table 4.17).

Material recycling results in a credit corresponding to the fact that it enables a subsequent avoidance of the production of virgin material. Each material obtained in the End-of-Life is credited with the environmental burdens associated with the material the recovered fraction is substituting. Thermal energy recovery (incineration) results in credits for power and thermal energy. Natural gas is assumed to be used for this energy transformation.

| Construction material | Waste treatment plan | Recycling/ recovery credit | Collection rates | |
|-----------------------|--|---|------------------|--|
| Glass waste | Landfill for inert matter (glass) | - | 100% | |
| Construction waste | Landfill for inert matter (construction waste unspecified) | - | 100% | |
| Aluminium waste | Aluminium recycling | Material credit | 95% | |
| Steel waste | Steel recycling | Material credit | 98% | |
| Foam plastics waste | Incineration | Credit for electricity and thermal energy | 80% | |
| PVC waste | Incineration | Credit for electricity and thermal energy | 80% | |
| Wood | Incineration | Credit for electricity and thermal energy | 80% | |
| Concrete | Minerals to inert landfill | - | 100% | |
| Other minerals | Minerals to inert landfill | - | 100% | |
| Stones | Minerals to inert landfill | - | 100% | |
| Coating and sealing | Coating and sealing recycling | Credit for electricity and thermal energy | 100% | |
| Waste (untreated) | Landfill for inert matter (construction waste unspecific) | - | Variable | |

 Table 4.17
 Overview of possible waste treatment plans

4.5.4.1 Material credit for steel and aluminium waste

The dataset represents an EOL scenario assuming closed loop recycling with a collection rate of 98% (steel) and 95% (aluminium) and average losses during recycling. It includes the "avoided burden" of the recycling product calculated by system expansion. This dataset corresponds with the datasets for the production of galvanized steel sheet and the production of anodized aluminium sheet. It can be used in the supply chain situation of the respective commodity in a representative manner.

The recycling potential describes the ecological value of a material's accumulation in the technosphere. It states how many environmental burdens may be avoided in relation to a new production of the material (avoidance of primary steel or aluminium production). Taking into account this collection rate and today's technologies in metal recycling, an amount of 65% primary steel or aluminium for the production of one kg steel or aluminium sheet is assumed. Since the recycling potential when manufacturing the product represents a saving, it is composed of a complete dataset with full characteristics.

If the complete recycling potential is used, the characteristics for manufacturing the product are lowered by those for the recycling potential.

5 Life cycle assessment results

Having modelled the 72 building types by using the above described generic model, the life cycle impact assessments were performed. The evaluation of the LCA results is exemplarily presented in Section 5.1. The full results for each building type are given in Annex C. Section 5.2 presents a synopsis of all life cycle based results for the individual building types. For orientation purposes, relevant building type information, concerning the technical description of each building type, is given in Annex C. In Section 5.3, the environmental impacts at EU-level are presented.

The results for the conducted LCAs for all building types are the basis for identifying environmental hotspots (Section 5.4). These hotspots are then used to define improvement options and to finally calculate improvement potentials (see Chapter 6 and Chapter 7).

5.1 Detailed results at building level

Each of the 72 building types was evaluated separately and the detailed results are systematically presented in Annex C. The following information illustrates how these results are presented and how they should be interpreted. For each building type, the results of the Life Cycle Assessment are presented in one table and one figure (see Table 5.1 and Figure 5.1 as an example for the building type Z1_SI_001).

| | PE* | GWP | GWP | GWP | | | | |

 Table 5.1
 Example of the LCIA results table for building type Z1_SI_001 (Annex C)

* PE: Primary Energy; GWP: Global Warming Potential; AP: Acidification Potential; EP: Eutrophication Potential; POCP: Photochemical Ozone Creation Potential; ODP: Ozone Depletion Potential

** Total = Use Phase

a) Greenhouse gas emissions resulting from fuel combustion and industry processes; b) incorporated greenhouse gases related to the carbon content of the used renewable resources like wood (see also Section 4.1)

Each result page contains a table which gives an overview of all considered environmental indicators and of the impacts from the different life cycle phases (see Table 5.1). The contributions are also given as relative shares. The sum of the Use Phase and the Construction Phase is considered to be 100% (for existing buildings, only the Use Phase is taken into account) and the End-of-Life impacts or credits are indicated as additional (positive or negative) impacts relative to 100%.

The table (Table 5.1) displays the absolute contributions from the life cycle phases (the Use Phase is separated into Heating & cooling, and Refurbishment) and the End-of-Life (EOL) is separated into EOL from construction and EOL from refurbishment.

The second element of the LCIA synopsis is a graph which displays the primary energy consumption associated with each building element and aspect, also showing the respective shares of the non-renewable and renewable primary energy (Figure 5.1).

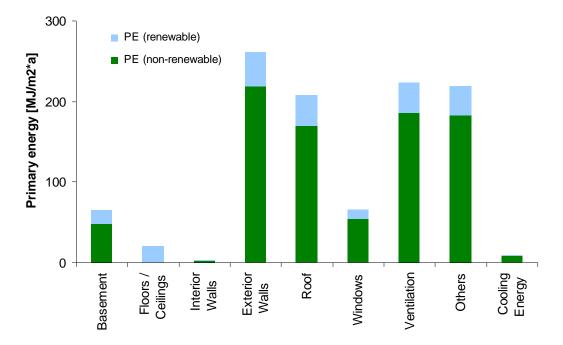

Figure 5.1 Example of the results of the LCA for one building type The contributions of all life cycle phases from the building elements for the indicator "Primary Energy" are displayed

These detailed results are the basis for the next sections showing the influence of the different building parameters and zones, and highlighting the most important life cycle phases contributing to the environmental impacts.

5.2 Life cycle impacts of the individual building types

5.2.1 Life cycle impacts according to zones and building types

Figure 5.2 to Figure 5.8 display the synoptic results for all building types, separated into the geographical zones as well as into the groups of building types for the consumption of Primary Energy (non-renewable), Primary Energy (renewable), Global Warming Potential, Acidification Potential, Eutrophication Potential, Photochemical Ozone Creation Potential,

and Ozone Layer Depletion Potential. The environmental impacts include Use Phase and Endof-Life for existing buildings and, for new buildings, Construction Phase, Use Phase and Endof-Life. New building types are indicated with blank symbols.

In each graph, the total life cycle impacts are represented by the midpoint indicators, expressed per m^2 and per year.

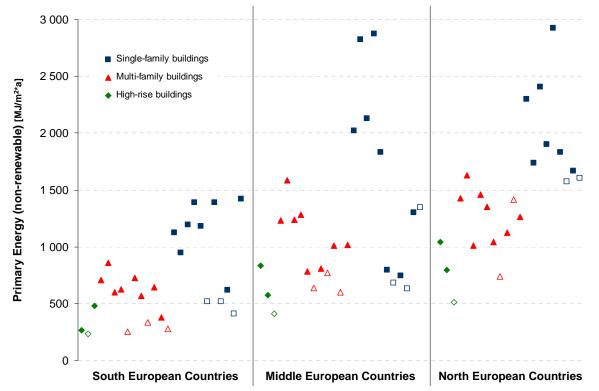

Figure 5.2 Life cycle impacts of all building types for the environmental indicator "Primary Energy (non-renewable)" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

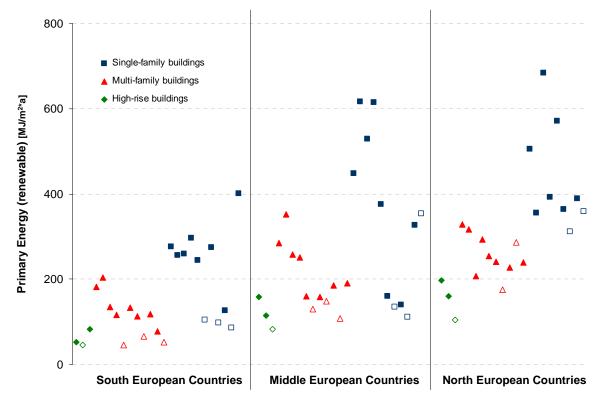

Figure 5.3 Life cycle impacts of all building types for the environmental indicator "Primary Energy (renewable)" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

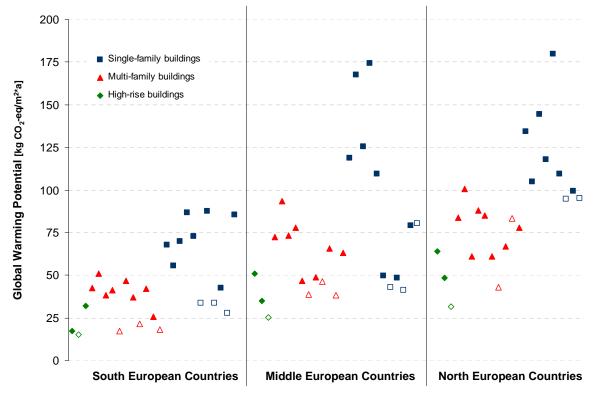

Figure 5.4 Life cycle impacts of all building types for the environmental impact category "Global Warming Potential" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

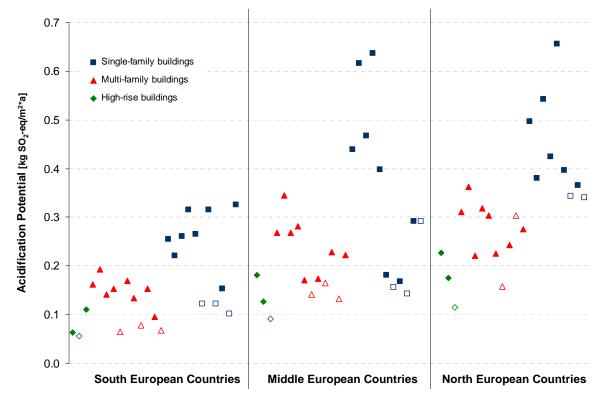

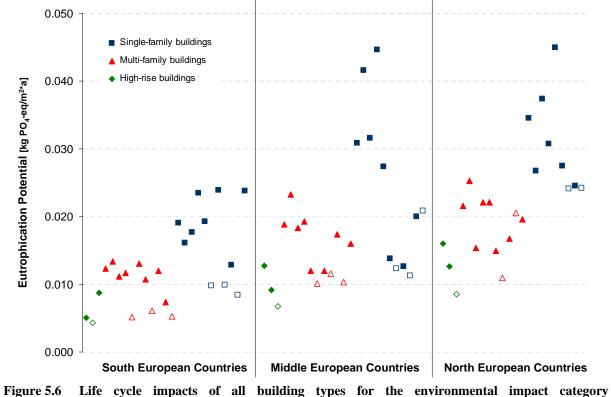

Figure 5.5 Life cycle impacts of all building types for the environmental impact category "Acidification Potential" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

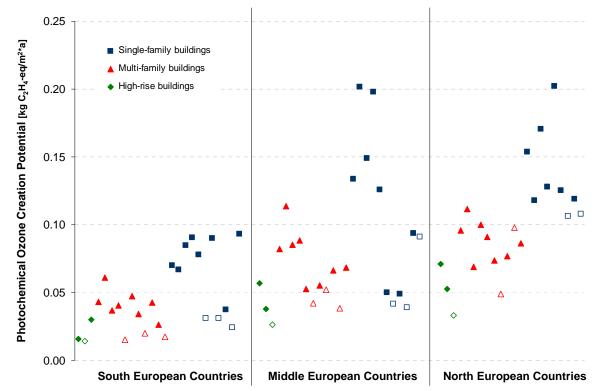

Figure 5.7 Life cycle impacts of all building types for the environmental impact category "Photochemical Ozone Creation Potential" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

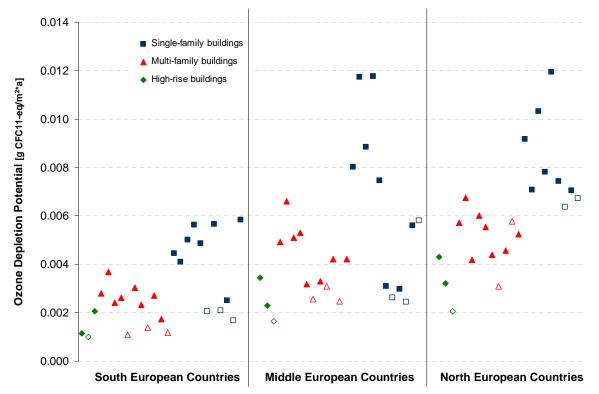

Figure 5.8 Life cycle impacts of all building types for the environmental impact category "Ozone Depletion Potential" New building types are indicated with blank symbols and correspond to the existing building type to the left of them

The graphs (Figure 5.2 to Figure 5.8) show common patterns throughout most impact categories.

In general, high-rise buildings have very similar life cycle impacts while higher deviations in total impacts exist for multi-family houses. The deviations of the life cycle impacts within the single-family houses are even higher. The graphs also show that this finding holds true for all geographical zones.

They also clearly show that the life cycle impacts of buildings in zone 1 (southern European countries) are, on average, lower than those associated with buildings in the two other zones. This trend is clearly visible for high-rise buildings and, to a lesser extent, for multi-family buildings while the deviations between single-family houses are generally too high to identify such a trend.

Another visible trend in these graphs is that the high-rise buildings have the lowest life cycle impacts. On average, single-family houses have the highest impacts.

These three general trends all result from the influence of the climatic conditions, the building shape (area:volume ratio) and the insulation level on the energy demand for heating (see Section 5.4.2).

When new buildings and existing buildings are compared, it can be seen that new buildings generally have better environmental performances than the corresponding existing building.

5.2.2 Life cycle impacts according to life cycle phases

The environmental impacts according to life cycle phases are displayed in Table 5.2 (existing buildings) and Table 5.3 (new buildings). The ranges of the contributions of each life cycle phase grouped according to geographical zone and building type are displayed (minimum and maximum shares).

It should be noted that, as a definition, the Use Phase of existing buildings amounts to 100% of the impacts (see Section 5.1). For the End-of-Life phase, negative values can be observed, as a result of recycling credits (see Section 4.5.4).

In most cases, the End-of-Life does not exceed 5% (blank and pale yellow cells in Table 5.2) of the impacts from the use phase of existing buildings. For some impact categories (Acidification, Eutrophication, Photochemical Pollution, and Ozone Depletion), the End-of-Life contribution ranges from negative to positive values. For GWP (net emissions), and for Primary Energy in zone 1, the contribution of the EOL is up to +9.3% (single-family houses). To a lesser extent, this also holds true for Eutrophication Potential (up to 4.5%).

In general, the relative contribution of the End-of-Life is more important in zone 1 than it is in the other zones. This is explained by lower environmental impacts during the Use Phase (due to lower heating energy demand) as already shown in Section 5.2.1. The share of the End-of-Life in southern Europe thus is only greater in relative terms compared to the middle and northern European countries.

| Zone | e Group | Life Cycle Phase | PE (total) | GWP (net) | AP | EP | POCP | ODP |
|-------|----------------------|-----------------------|------------|-----------|------------|------------|------------|------------|
| 1 | SI | Use Phase | 100 | 100 | 100 | 100 | 100 | 100 |
| | | End-of-Life | 1.1 - 9.3 | 1.1 - 9.3 | -0.7 - 2.2 | 1.3 - 4.5 | -0.2 - 0.6 | -3.7 - 0.1 |

Table 5.2Range of the share (%) of the contribution of the life cycle phases to the environmental
impacts for each geographical zone and building type group (existing buildings)

For new buildings (Table 5.3), per definition, the sum of the Construction Phase and the Use Phase is considered to be 100% of the impacts (see Section 5.1). Again, for the End-of-Life phase, there can be negative values as a result of recycling credits (see Section 4.5.4).

In general, the Use Phase dominates the environmental impacts and contributes (for all building groups and zones) for more than 50% (in all cases). Its share can even reach 97%. The Construction Phase also contributes to the impacts and can reach considerable shares (up to 50% in the case of single-family houses in zone 1 and Eutrophication Potential). The End-of-Life phase is of minor relevance for all zones and building groups. The maximum levels reached are 8% for single-family houses in zone 2 and 6% for multi-family houses in zone 3. In most of the cases, the End-of-Life share does not exceed 5%.

Similar to the existing building types, there are some general trends for the new building types as well. Within each zone, the significance of the Use Phase usually increases from single-family houses to multi-family houses and then to high-rise buildings with an exception for the high-rise buildings in the northern European countries (zone 3). This again, is due to relatively fewer environmental impacts during the Use Phase (due to lower heating energy demand) for multi-family houses and high-rise buildings when compared to single-family houses. For all building groups, the importance of the Use Phase increases from zone 1 to zone 3 in general. The reason for this trend is the comparatively higher heating energy demand in middle and northern European countries compared to zone 1, which leads to a relatively higher share of the Use Phase when compared to the Construction Phase and the End-of-Life.

It should be borne in mind that the significance of the Use Phase also depends on the assumed residual service life for new buildings. The service life was estimated to be 40 years or longer but the Use Phase was restricted to 40 years (see Section 4.3.2). Thus, for some building types, the significance of the Use Phase could even be higher if the full residual service life of the building type is taken into account for the Use Phase.

5.3 Environmental impacts at EU level

The environmental impacts of the 72 single building types were aggregated at EU level by multiplication with the respective building stock (living area in Mio. m^2). Figure 5.9 displays the results of the aggregation for the impact category "Global Warming Potential". The results for the other impact categories show similar patterns (this will be discussed in detail in Section 5.3.2 below).

First, the environmental impacts from new buildings can be seen to be negligible when compared to the impacts from existing buildings (share is 1.2%).

Second, the results show that zone 1 (23.6%) and zone 2 (69.6%) dominate the environmental impacts. Zone 3 is responsible for only 6.8% of the environmental impacts. This is primarily due to the low percentage share of living area in the north European countries (4.0%) when compared to zone 1 (42.9%) and zone 2 (53.1%) which completely outweighs the – generally – higher environmental impacts per m^2 in northern Europe as a result of colder weather conditions (see Section 5.2.1).

Third, the results suggest that single-family and multi-family houses dominate the environmental impacts at EU level. This finding will be discussed in greater detail in Section 5.3.2. Only five to ten building types dominate the environmental impacts (due to their high percentage share of living area).

indicator "Global Warming Potential"

5.3.1 Environmental impacts according to life cycle phase

Figure 5.10 illustrates, at aggregated EU level, the dominance of the Use Phase in the environmental impacts of the existing residential building stock in the EU-25. The End-of-Life accounts for only -1.3 to 2.7% of the environmental impacts. For Primary Energy (non-renewable and renewable), and Ozone Depletion Potential, the End-of-Life Phase contribution is negative, i.e. the End-of-Life comes with credits due to material recycling (-1.3 to -0.1%). For GWP, Acidification Potential, Eutrophication Potential and Photochemical Ozone Creation Potential, the End-of-Life exhibits positive environmental impacts (0.1 to 2.7% when compared to the impacts from the Use Phase).

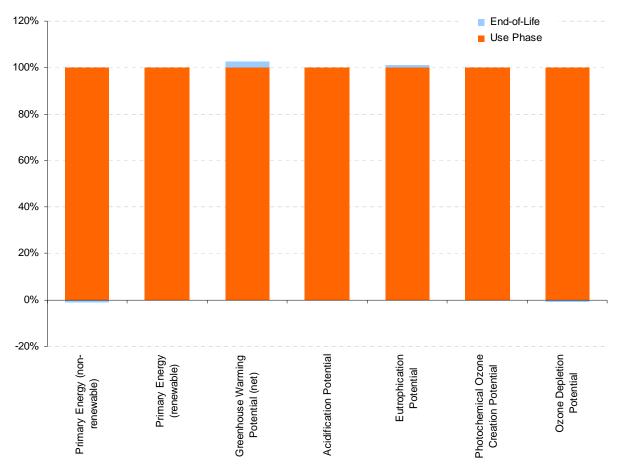

Figure 5.10 Total environmental impacts of the building stock in the EU-25 according to life cycle phases (existing buildings)

For new buildings, the Use Phase also dominates the total environmental impacts at EU level, but the Construction Phase also accounts for a great percentage share of the impacts (Figure 5.11). The Construction Phase is responsible for 8.3 to 34.3% of the environmental impacts. The percentage share is highest for Eutrophication Potential (34.3%) and lowest for POCP (8.3%).

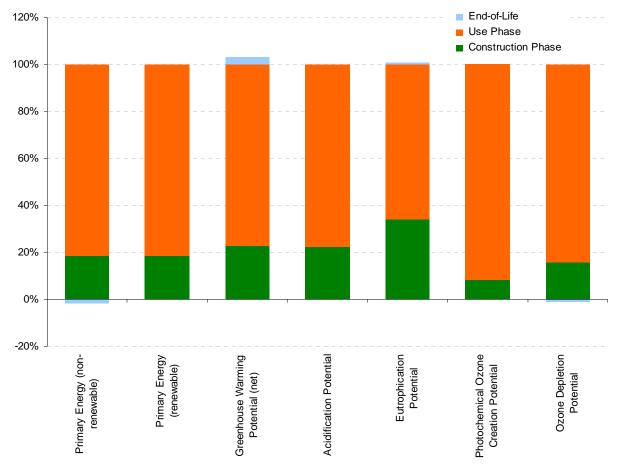

Figure 5.11 Total environmental impact of the building stock in the EU-25 according to life cycle phases (new buildings)

Again, the End-of-Life is of minor importance only (-1.7 to 3.2% of the environmental impacts). For Primary Energy (non-renewable and renewable), and Ozone Depletion Potential, the End-of-Life comes with credits while for GWP, AP, EP and POCP, the End-of-Life shows positive environmental impacts.

5.3.2 Environmental impacts according to geographical zone and building group

When grouped according to geographical zones, the majority of the environmental impacts can be seen to occur in zone 2 (middle European countries) with 69.2 to 69.7% of the environmental impacts at EU level (Figure 5.12). Zone 1 (southern European countries) is responsible for 23.5 to 24.1% of the impacts. Zone 3 only plays a minor role (6.7 to 6.8%). When compared to the living area, zone 2 represents a higher percentage share of the environmental impacts than the percentage share of living area would suggest (53.1%). The same holds true for zone 3 (4% of living area). For zone 1 (42.9%), the respective environmental impacts are smaller than the share in living area. This can be explained by lower environmental impacts generally of the building stock of zone 1 per m² when compared to the building types in the other zones (see Section 5.2.1).

5

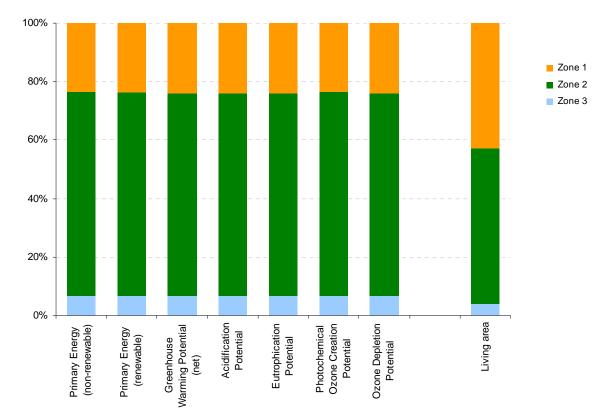

Figure 5.12 Relative contributions to the total environmental impacts of the building stock in the EU-25 according to geographical zones

Figure 5.13 displays the environmental impacts at EU level grouped according to building groups. The majority of the environmental impacts are due to single-family houses (63.3 to 64.0%), followed by multi-family houses (31.9 to 32.3%). High-rise buildings account for 4.1 to 4.4% of the environmental impacts only. Again, the shares in environmental impacts can be compared to the respective shares in living area. Single-family houses exhibit higher relative shares in environmental impacts than their share in living area would suggest. This is due to their relatively higher environmental burdens per m² living area as shown in Section 5.2.1. In contrast, for multi-family houses, and especially for high-rise buildings, their respective environmental impacts are smaller than their shares in living area.

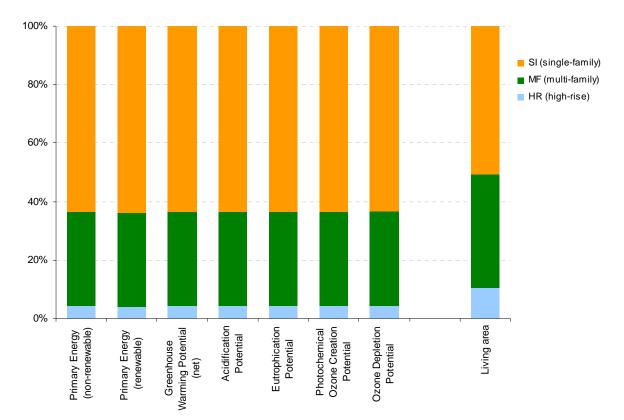

Figure 5.13 Relative contributions to the total environmental impacts of the building stock in the EU-25 according to building groups

The total environmental impacts show a similar pattern for all impact categories and impact indicators (see Figure 5.12 and Figure 5.13). To a large extent, this reflects the dominance of existing buildings in these impacts, where the use phase, and especially energy use for heating, is the greatest source of impacts.

5.4 Environmental hotspots

5.4.1 Introduction

The previous sections showed the large dominance of the Use Phase in the overall life cycle impacts of buildings (see Section 5.3.1). It also showed the respective importance of the geographical zones in terms of environmental impacts from residential buildings. In this section, the impacts from the Use Phase and of the Construction Phase (in the case of new buildings) are further detailed and analysed with a view to identifying the building components that generate the greatest impacts.

In both cases, the LCIA results given in Annex C for each building type are rescaled at zone/EU level and aggregated in order to highlight the average contribution of the different building elements.

5.4.2 Use phase

5.4.2.1 Energy performance of buildings

Building types differ from one to another in various ways. One of the most important differences which influence the (heating and cooling) energy demand is the envelope surface: volume ratio that is calculated as the quotient of the heat transferring envelope area to the volume of the building. A multi-family house generally shows a smaller envelope: volume ratio than, e.g. single-family houses. The values range between high-rise buildings with values of below $0.4 \text{ m}^2/\text{m}^3$, to multi-family houses with values from $0.4 \text{ to } 0.8 \text{ m}^2/\text{m}^3$, up to single-family houses of between $0.8 \text{ and } 1.2 \text{ m}^2/\text{m}^3$. This ratio has a significant influence on the heating energy consumption per m² living area and therefore affects the Use Phase of the building, yielding different outcomes of the Life Cycle Impact Assessments (see Section 5.2.1).

Between the different geographical zones, the major differences lie in the monthly average temperature, as well as in the monthly diffuse and global solar radiation, which vary significantly between the zones.

To a certain extent, the envelopes of buildings in Europe are already adapted to the local weather conditions. Buildings in Northern Europe are, for instance, generally designed with a higher level of thermal insulation to better reduce the heat transfers. This was taken into account when determining the boundary conditions of zone specific buildings.

All these three factors combined largely explain the energy and environmental profile of the buildings modelled in the project. The influence of these factors is shown in Figure 5.14 which displays the average primary energy demand per m² living area and per year in the different zones and for the different building types (including existing and new buildings). The impacts were aggregated for all building types (separately for existing and new buildings) belonging to the respective building group (SI, MF, HR) and zone and then the averages were calculated. In this case, Primary Energy (total) was used as an indicator, which is a good proxy for the environmental impacts (see Section 5.3.2).

It is worth emphasising that, despite the fact that the energy demand from buildings in zone 3 is the highest, this does not differ from the buildings in the other zones proportionally to the average heating degree days (1269, 3272, 4513 HDD in zone 1, zone 2 and zone 3 respectively). This is explained by the higher insulation level of these buildings when compared to those in the other zones.

5.4.2.2 Hotspots

The environmental impacts from the use phase were allocated to the different building elements according to their role regarding heat losses. Figure 5.14 displays the contribution of the individual building elements to the environmental impacts of the Use Phase. These heating losses ("others")⁴ will not be included into the hotspot analysis.

As shown before, there is a clear pattern of increasing environmental impacts when travelling from southern to northern Europe and decreasing environmental impacts when moving from single-family houses to multi-family houses to high-rise buildings (see Section 5.2.1). It

⁴ The heating losses through technical and rejects (summarised as "others") are due to non-steady temperature distribution, non-optimal room temperatures and heating control, heating losses of the heat distribution system, heat generation losses in operation and standby, and heat losses due to non-optimal control of the heating system. Rejects represent non-used heating gains.

should be borne in mind that only a small percentage of the environmental impacts are due to the northern European countries (zone 3) because of the small percentage share in living area of this zone (see Figure 5.12).

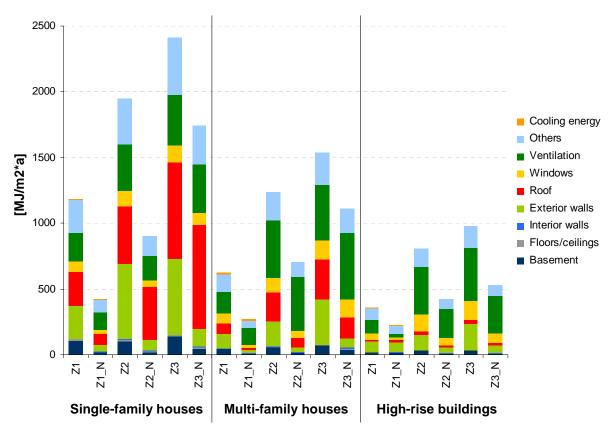

Figure 5.14 Contribution of the individual construction elements to the environmental impacts of the Use Phase (total Primary Energy) according to zone and building group (weighted average) _N denotes new buildings

Figure 5.14 first suggests a common pattern across the different zones and building types, namely the significant importance of heat losses, associated with building ventilation. Heat losses through roofs and external walls are also important for a majority of single-family and multi-family houses. In these cases, however, both the absolute and relative levels vary from one building type to another. The relative importance of heat losses from external walls in high-rise buildings is also significant, but, roofs are of low importance in the case of high-rise buildings. This results from both the lower share of roof surface to the total building envelope surface and from a higher insulation level.

For single-family and multi-family houses, the percentage heat losses through windows are smaller, because the corresponding surfaces involved are smaller, but also as a result of the underlying assumption that window retrofitting is, to some extent, part of an autonomous evolution in existing buildings and that it will take place during the life of the buildings. Their relative importance is, however, important for high-rise buildings.

The better energy performance of new buildings is also visible in this graph, reflecting the higher insulation standards these buildings fulfil.

Zone 1

For existing **single-family houses**, the roof and the exterior walls are the most important hotpots followed by ventilation. For new single-family houses, ventilation dominates the environmental burdens from the Use Phase, followed by the roof and the exterior walls.

Concerning **multi-family buildings**, ventilation and exterior walls are the most important elements for both existing buildings and for new buildings.

The hotspots for existing **high-rise buildings** are ventilation and exterior walls. For new HR buildings, the most dominant building elements from an environmental point of view are exterior walls and ventilation.

The heating losses through windows show some hotspots from an environmental point of view (existing multi-family houses and existing high-rise buildings). In existing single-family houses, the roof is of importance as well. The basement, floors/ceilings, interior walls and cooling energy only play a relatively minor role.

Zone 2

In general, existing **single-family houses** show that most of their environmental impacts relate to heating losses through the exterior walls followed by heating losses through the roof. For new single-family houses, the roof and ventilation show major impacts.

For existing and new **multi-family houses**, ventilation losses play a major role followed by the losses through the roof.

The environmental impacts of **high-rise buildings** during the Use Phase are dominated by ventilation losses of heating energy, windows, and exterior walls.

As in zone 1, the building elements basement, floors/ceilings, interior walls and cooling energy only play a minor role both for existing and new buildings.

Zone 3

Similar to the middle European countries, existing **single-family houses** in the northern part of Europe have most of their environmental impacts in heating losses through the roof and exterior walls. Ventilation losses occupy the third position. For new buildings, the roof is the most important building element, followed by ventilation.

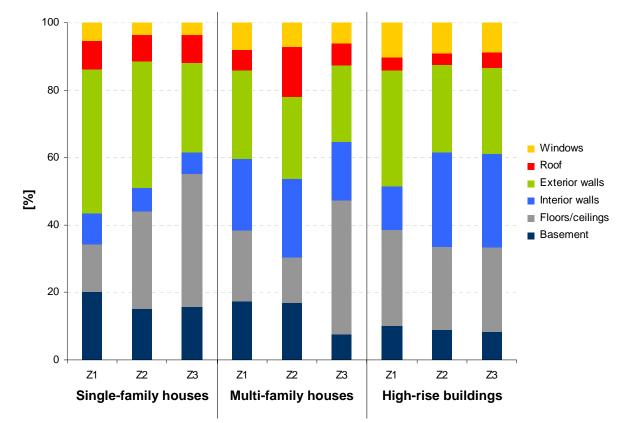

Multi-family houses in this zone are quite similar to the middle European countries: Ventilation losses, heating losses through exterior walls and roof represent the hotspots of the Use Phase for this building group.

As for high-rise buildings, ventilation, exterior walls and windows dominate the use phase.

As for the other zones, the building elements basement, floors/ceilings, interior walls and cooling energy only play a minor role both for existing and new buildings.

5.4.3 Construction phase

The contributions of the single building elements to the environmental impacts of the Construction Phase are shown in Figure 5.15,. The impacts were aggregated for all new building types belonging to the respective building group (SI, MF, HR) and zone and then the averages were calculated. The total Primary Energy was used as an indicator for the

environmental impacts, which is a good proxy for the environmental impacts (see Section 5.3.2).

Figure 5.15 Contribution of the individual construction elements to the environmental impacts of the Construction Phase (total Primary Energy) for new buildings according to zone and building group

In all three zones, the exterior walls, the basement, and floors/ceilings are important. Interior walls, roof and windows play a minor role only.

The geometry and volume obviously influences the role of the different building elements. For instance, exterior walls tend to play a smaller relative role for high-rise buildings than for the others.

5.5 Robustness of results

For all building models, completeness checks were carried out for the overall mass of the construction materials, for the calculated energy in the use phase and for all end-of-life processes on a construction component level. All input data were internally reviewed to ensure the completeness of the life cycle models with regard to masses, areas and refurbishment cycles of the building elements.

Due to the fact that the life cycle models portray the input information, sensitivity analyses focused on the most relevant life cycle parameters were performed. The dominating environmental effects of the use phase show the relevance of good input data for heating and cooling energy demands. Similar results hold true for some aspects of the end-of-life phase, especially of existing buildings.

5

Before adapting the generic life cycle model to the specific building types, a consistency check was carried out. Consistent background processes were chosen, which ensured similar definitions for the system boundaries, cut-off criteria and other underlying modelling aspects. In the foreground system, the use of building elements, transport and energy requirements were defined consistently throughout all life cycle models. Hence, the inclusion and omission of life cycle aspects is similar in all LCAs.

6 Options for improving the environmental performance of residential buildings

The environmental hotspots derived in Section 5.4 are the basis for the definition of technical improvement options. The environmental life cycle impacts quantified in Chapter 5 and the derived environmental hotspots provide a sound basis for focusing the analysis of environmental improvements to the Use Phase and especially space heating and, in the case of new buildings, to the Construction Phase.

This chapter describes the improvement options considered for further analysis. The environmental improvement and costs of these measures are hereby quantified.

6.1 Improving the energy performance of existing buildings

In the case of existing buildings, energy efficiency can be improved by implementing higher thermal insulation levels on the envelope components (e.g. roof, external walls). In view of the environmental hotspots identified in 5.4.2.2, the most significant improvement options are:

- replacement of windows
- additional façade insulation
- additional roof insulation
- new sealings to reduce ventilation losses.

In the following information, the retrofit measures are described in terms of the general practices that reflect the best available techniques currently available in the EU-25. Measures which increase environmental performance may exist but they may also be technically less feasible or too expensive. The commonly used measures are listed in Table 6.1, with a short description regarding the techniques and materials involved (e.g. a thickness of the insulation board of 12 cm from ETICS - Exterior Thermal Insulation Composite System) and were derived from polls done during the European COST C16 action [BRAGANÇA 2007].

This project is not aimed at giving any detailed instructions on how to apply a measure. However, it has to be kept in mind that, in practice, the detailed carrying out of the measures has to suit the individual buildings.

| Building element | Measure | Description | | |
|---------------------|--|---|--|--|
| Exterior walls | Insulation plaster | Insulation plaster is sometimes used when either proper insulation with insulating boards is too costly or when the existing joints to, e.g. the roof, do not allow a thicker insulation | | |
| | External thermal insulation composite systems (ETICS) | The most commonly used system utilises polystyrene, mineral wool, recycled material or environmental friendly material as insulation material | | |
| | Core insulation: insulation between the wooden construction and parts of the wooden construction or insulation between masonry and curtain walling | This is the cheapest way of applying insulation to walls by just pumping insulation material into the core of the wall | | |
| | Interior insulation | If the building situation (e.g. the façade is regarded as national heritage) does not allow external insulation, this way of insulation is taken into account. The interior insulation can cause various problems with thermal bridges and stress of the load-bearing structure | | |
| Roof | Sloped roof: insulation over, between and under the spars; insulation of the roof floor | For sloped roofs, either the ceiling floor is insulated or the insulation is put under, between or over the spars, depending on whether the ceiling is inhabited and depending on the degradation state of the roof tiles | | |
| | Flat roof: insulation of the flat roof either by cold or warm roof | For flat roofs, in most cases, the retrofit measure of new insulation is applied when the flat roof is not waterproof any more and therefore the insulation would be affected by the replacement action, as well | | |
| | Wooden construction: wooden joists, roof battening | If a wooden construction is not load-bearing any more, due to humidity and fungal attack, the roof cladding is removed and a new roof framework is implemented | | |
| | Cladding: roof tile, bituminous layer, metal layer | The lower levels of the building have to be protected from rain and other environmental impacts | | |
| Basement | Insulation of the basement ceiling | Generally, in the basement/cellar, the temperature is lower than the necessary ambient temperature for living spaces. Therefore, the heat flux to these colder areas has to be reduced | | |

 Table 6.1
 Improvement measures considered for existing buildings

6.1.1 Replacement of windows

The replacement of old, e.g. single glazed, windows by modern double glazed coated and gas filled glazing with corresponding optimised frames reduces ventilation and transmission losses tremendously while also improving the thermal comfort within the living spaces by reducing radiation losses and reducing the acoustic impact from outside. As improved glazing systems require larger frame structures and have a lower transmission coefficient (g-value), less radiation in the infra-red radiation but also in the visible spectrum is transmitted to the room. On the one hand, overheating, especially in summertime, accordingly reduces the cooling load which is a positive effect. On the other hand, less daylight within the room after the retrofit action occurs.

It should also be emphasised that in old buildings with high transmission losses through exterior walls mould and fungus growth is being recorded (especially on thermal bridges) through reduced ventilation losses caused by the new windows. Therefore, a replacement of the windows should be ideally coupled with an overall improvement of the thermal losses of the building envelope.

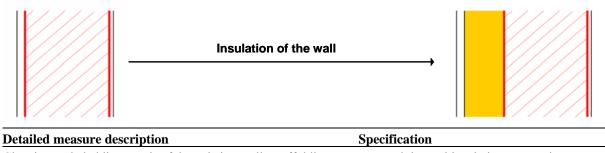

The replacement of windows is assumed to take place anyway in the base scenario after 10 years. The assumption of window replacements during the use phase comes from the outcome of the European research project INVESTIMMO, in which the life cycle and the degradation potential for windows were analysed. The most important factors that influence the degradation and, consequently, the replacement of windows were identified as follows:

- frame type (wood, plastic, aluminium, wood and metal)
- frame paint (plastic, oil, weather resistant, anti-corrosion paint)
- quality of windows
- age
- building ownership status (public, private company owning more than four buildings, private company owning fewer than four buildings, one owner, many owners or finally craft guilds).

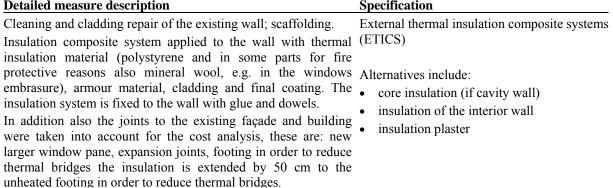

The measure 'replacement of windows' is nevertheless crucial as this measure might also lead to problems of reduced air change rate and corresponding air quality reduction, mould and fungus growth. For all measures but especially for window replacements and the reduction of ventilation losses, the advice of experts in building physics should be performed.

6.1.2 Additional façade insulation

Thermal insulation of the external walls reduces transmission losses and the corresponding radiation losses which increases the thermal comfort of the inhabitants. This can be done by putting layers of insulation material with low heat conductivity (around 0.040 W/mK) either on the internal wall, in the core (in case of cavity insulation), or as external insulation on the outer side of the wall (see Table 6.2). Problems with thermal bridges and thermal stress of the load-bearing structure are best avoided with external insulation.

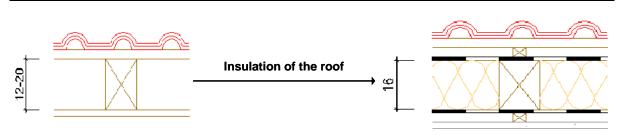

6.1.3 Additional roof insulation

The roof retrofitting with additional insulation will depend on the type of roof. In the case of sloped roofs, the insulating layer can be put under, between or over the spars. For flat roofs, insulation can be implemented as "cold roof" or "warm roof" (see Table 6.3). Also the insulation of the attic floor is common practice because of the low cost. As already described above, roof insulation also reduces transmission losses and the energy demand by simultaneously increasing the thermal comfort of the inhabitants of the highest floor in the building.

| Detailed measure description | Specification |
|---|--|
| Scaffolding with removal of existing roof covering (e.g. tiles, battening and vapour barrier), insulation (mineral wool) put between and over the rafters with subsequent covering measures of the roof by again putting the roof covering on the roof. The cheaper measure of putting an insulation between and under the rafters from below without removing the roof covering was not taken into account as this measure cannot be performed in inhabited attics where the rafters are usually covered by plasterboards. | Insulation over the rafter Insulation between rafter Insulation of top ceiling |

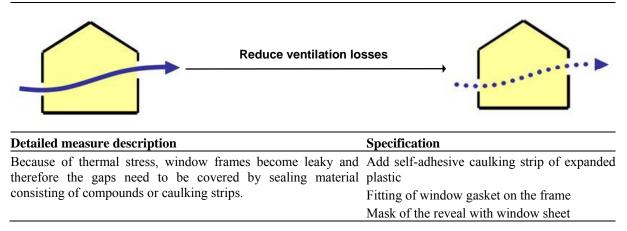

6.1.4 New sealings to reduce ventilation losses

For the sake of the well being and the comfort of the inhabitants, a minimum air change rate is essential for providing sufficient quantities of oxygen and for reducing the CO and CO_2 concentrations in the room. The minimum air change rate in national standards depends on the intended use of the room. For living spaces, in most cases, the minimum air change rate is intended to be as high as 0.3 to 0.5 /h. The air change rate also contributes to the reduction of the relative humidity in the room and thus the risk of mould and fungus formation. These aspects have to be taken into account when considering means to reduce ventilation losses and consequently to reduce energy losses.

The reduction of ventilation losses is a low-budget measure that can normally be performed simply by adding self-adhesive caulking strips of expanded plastic on the window frame and other parts of the house where high ventilation losses occur (see Table 6.4). Normally, a thermographic analysis of the building shows losses through, e.g. roller shutter boxes, sockets and, in the roof, through the gaps between the roof tiles.

The replacement of old windows also leads to a reduction of ventilation but this is only true for the first years after the installation of the new windows. Due to thermal and moisture stress, as well as through the usage of movable parts, the window frames do not close tightly a few years after their installation.

6.2 New buildings

6.2.1 Better energy efficiency

As shown in Section 5.4.2.2 and Section 5.2.1, new buildings have higher energy efficiency when compared to existing ones. This is the consequence of better construction practices which already implement higher insulation standards to the different building envelopes due to current policy regulation, including the Directive on the energy performance of buildings (EPBD) and its use in Member States.

This is the reason why such measures were not analysed within this project. It should be noted, however, that, in reality, the level of implementation and use in different Member States varies substantially, and that where delays are observed, lower insulation standards are applied.

It is also worth noting that, due to the long life of buildings, newly erected buildings today represent only a small share of the overall building stock in Europe. On the other hand, the decisions taken today for these new buildings will highly determine the pressure of the residential sector on energy resources and on climate change in the future years. The long term strategy of the EU to reduce greenhouse gas emissions will rely on drastic emission reductions in all the sectors, including the residential sector. In this respect, further innovative construction designs play an important role. This includes the new concepts of passive housing and the so-called "zero CO₂ emission building" for which space heating demand is reduced to 20 kWh/m² [SMEDS & WALL, 2007]. Such a low demand is only achievable with the combination of optimal building geometry (A:V ratio), high thermal insulation of the whole envelope, high air tightness and ventilation systems with a high energy performance, including heat exchangers, and proper building orientation and windows surfaces to optimise solar gains during heating periods and shading devices to avoid overheating during cooling periods.

High energy performance can also incorporate better heating and cooling systems such as heat pumps or solar panels which may also entail some changes in the buildings. These new building concepts thus require a much more integrated approach of the different buildings aspects, including better performing heating and cooling systems. It is also more difficult to quantify the additional costs of these new buildings in a generic way⁵. The assessment of such innovative systems is beyond the scope of this project.

6.2.2 Alternative construction materials

Regarding the Construction Phase of new buildings which also represents a significant proportion of the environmental impacts of the buildings, some options for changing the material composition are feasible. Some alternatives were considered with a view to illustrate the possible achievable improvement. The selection of considered alternatives was made keeping in mind some technical requirements, e.g. acoustic protection and fire protection.

The technical design of basements and foundations, and restrictions due to the load-bearing character of the basements do not generally allow variations in construction materials. The same holds true for floors and ceilings, where variations in materials for a specific building type is also strictly limited and therefore not evaluated here.

As a result, the alternatives were focused on exterior and interior walls and were compared to the respective base scenario. This included:

- breeze concrete
- sandlime
- wooden construction
- cored brick
- reinforced concrete.

⁵ The cost could be as much as 40% of the normal price (see for instance <u>http://news.bbc.co.uk/1/hi/business/6735715.stm</u>).

7 Environmental benefits and cost efficiency

7.1 Existing buildings

The environmental potential and associated costs were analysed for the most representative buildings analysed in Chapter 5. In each case, the assessment was made in comparison to the relevant base case. The assessment was also made at the building stock level.

7.1.1 Considered building types

In order to keep the analysis feasible, while also focusing on the most important part of the building stock, the considered **existing** building types were selected to account for approximately 80% of the European residential building stock living area. This resulted in the list of building types given in Table 7.1.

| types | summing types account for 0070 0 | 8 | |
|---------------|--|---------------------------------|---------------------------|
| Building type | Total living area in million m² per building type | Share per building type in % | Accumulated share in % |
| Z2_SI_005 | 1 262 | 8.5 | 8.5 |
| Z2_SI_001 | 981 | 6.6 | 15.0 |
| Z1_MF_003 | 846 | 5.7 | 20.7 |
| Z2_MF_003 | 814 | 5.5 | 26.1 |
| Z2_SI_006_ex | 776 | 5.2 | 31.3 |

| Z1_HR_002 | 22 | 1.6% | 77.1% |
| Z1_MF_001 | 22 | 1.6% | 78.7% |
| Z2_HR_001 | 20 | 1.4% | 80.1% |

Table 7.2Existing building types analysed with regard to their environmental improvement potential.
These building types account for 80% of the life cycle greenhouse gas emissions of all
previously analysed building types

It should be noted that, as a result of this selection criterion, buildings from zone 3 and possible improvements are not considered. This of course, does not mean that improvement is not feasible in the countries. It can be expected, that, in some countries (Baltic countries), further building insulation would result in substantial energy efficiency improvements. On the other hand, this zone represents a small share of the building stock in the EU-25. Therefore, the exclusion of zone 3 buildings in this assessment will not entail a significant underestimation of the overall improvement potential associated with existing building insulation.

All suggested retrofit measures for existing buildings are intended to reduce the heating energy consumption. The environmental hotspots and the resulting improvement options yielded three different retrofit measures:

- applying additional insulation material to the roof
- applying additional insulation material to the façade
- replacing joint sealings on doors and windows to reduce ventilation losses.

These retrofit measures are applied to the building types according to the matrix given in Table 7.3, which is the result of the procedure detailed in Section 5.4, in conjunction with the considered building types from Section 7.1.1.

| Building type | Building stock in million m ² per building type | Environmental hotspots in the Use Phase (heating & cooling) | | | |

 Table 7.3
 Mapping of identified environmental hotspots onto the considered existing building types for defining improvement options

7.1.2 Improved building versus base case

Chapter 4 determined building types and related product systems representing base cases against which the improvement options ought to be assessed.

For each of the buildings listed in Table 7.3, and each considered retrofit measure, the generic model was adjusted with the corresponding parameter to calculate the new environmental profile of the building after retrofitting. These changed life cycle impacts were then compared to those estimated for the respective base case in order to quantify the environmental benefits of the measure. A similar approach was followed to quantify the additional costs entailed by the retrofitting measure (see Section 7.1.4). The comparison of the retrofitted building and the reference building has to be made cautiously, by taking into account all the changes that are likely to occur during the life of the building.

As already described in Section 4.5.3.3, some of the improvements are expected to be implemented any way to a certain fraction of the buildings. Certain parts have indeed to be replaced by parts of the buildings that are at least comparable in their functionality (refurbishment). In some cases, the buildings owners will consider that this is also the opportunity to improve the thermal insulation, especially when some policy incentives are already in place (e.g. subsidies, tax exemption). Therefore, to some extent, better thermal insulation of elements such as the roof or external walls will occur during the building life which was reflected in the base case.

Two types of further improvements can take place: on the one hand, these improvements could be applied more systematically when the building element is refurbished. On the other hand, the element retrofitting could be done earlier than what would occur autonomously.

Table 7.4 provides the description of the assumed changes for the reference building (refurbishment without any thermal insulation) and for the retrofitted building (refurbishment with thermal insulation) for respectively the three improvement measures analysed. This has to be taken into account when analysing the costs of the measures (see Section 7.1.4).

| | cription of the improvement measures | |
|---|---|---|
| Measure | Retrofitted building | Reference building |
| Additional façade insulation | ETICS (exterior thermal insulation composite system) – with insulation material 12 cm, fixed with dowels, armour, cladding and final paint. The ETICS is applied on existing cladding with corresponding preparation: cleaning and partial demolition of existing cladding. In addition, cost for scaffolding, royalty for planners, and accessory charges are included | demolition of existing cladding), new cladding and final paint In addition, cost for scaffolding, royalty for planners, and accessory charges are included |
| Additional roof insulation | Insulation of attic floor (uninhabited attic, sloped roof): Preparation of screed, levelling, insulation material 10 cm with connection cost (adaptation of attic entrance door, etc.) and final covering with walkable wooden floor Insulation over/between spars (sloped roof). Preparation including tile removal, insulation (16 cm) with vapour barrier, counter batten and tiles Insulation of flat roof. Preparation, removal of existing insulation and old bituminous layer, new insulation (16 cm), bituminous layer In addition, cost for scaffolding, royalty for planners, and accessory charges are included | floor with screed Sloped roof: Preparation including tile removal, new counter battens, vapour barrier and tiles Flat roof: New bituminous layer with removal of the existing one In addition, cost for scaffolding, royalty for planners, and accessory charges are included |
| New sealings to reduce ventilation losses | Self-adhesive caulking strip of expanded plastic put on all window frames in the building type | No alternative calculated |

|-----------|--------------------|--------------------|-------------------|
| Table 7.4 | Description | of the improvement | <i>i</i> measures |

7.1.3 Fuel savings

The implementation of insulation material on the roof and/or on the external wall, or the reduction of ventilation losses made on the existing building today will obviously reduce its energy demand for space heating and will make it perform better than in its reference case.

However, the comparison with the reference case has to take into account the already assumed autonomous improvement in the base case. As detailed in Figure 7.1 to Figure 7.3, some buildings are assumed to have their roof insulated after a certain period of time so that their final energy demand will be reduced accordingly. Windows are also assumed to be retrofitted after 10 years as part of an autonomous improvement.

For each building, the evolution of the final energy demand during the building life of both buildings has to be compared. This is shown in Figure 7.1 and Figure 7.2 in the case of the building Z1_SI_001 and the "roof insulation" and "façade insulation" improved cases.

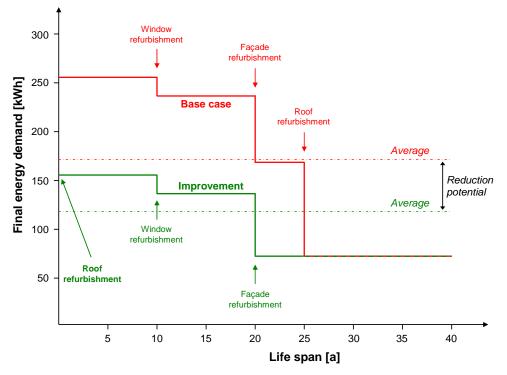

Figure 7.1 Final energy demand of the base case and improvement option "additional roof insulation"

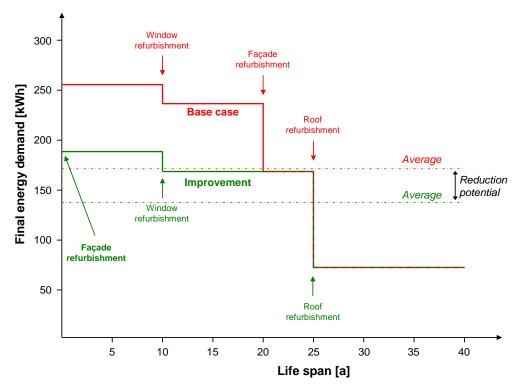

Figure 7.2 Final energy demand of the base case and improvement option "additional façade insulation"

In the improved case with reduced ventilation losses, the comparison of the improved building and the base case was limited to a 10 year time span (see Figure 7.3). This choice was guided by the fact that, one important share of the fuel savings assumed to be achieved with better sealings is relating to reduced gaps in windows. In the base case, it is assumed that

windows are retrofitted after 10 years. Therefore, it should be expected that this retrofitting will also result in reduced ventilation losses. In addition, in the cases where roof retrofitting is also considered during the residual life of the base case building, some indirect effect on ventilation losses should also be expected. Considering a time horizon longer than 10 years would thus be misleading as it would result in distorted results.

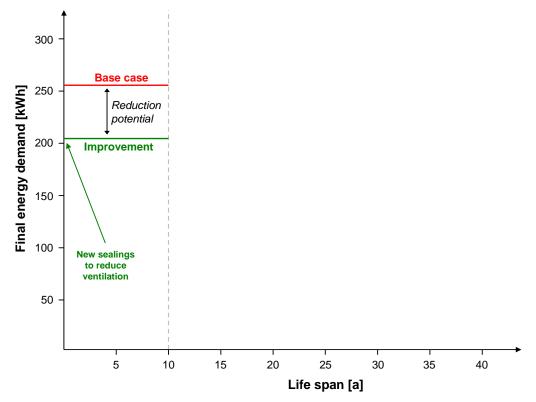

Figure 7.3 Final energy demand of the base case and improvement option "new sealings to reduce ventilation"

The overall description of the assumptions made per building is shown in Table 7.5 which gives the U-values per building element as assumed in the base case (initial value and, when relevant, the value after refurbishment) and in the improved case.

| Building type | Exterio | Exterior wall | | Roof | | Window | |
|---------------|---------|---------------|--------|-------|--------|--------|--|
| | Before | After | Before | After | Before | After | |
| Z1_SI_001 | 1.10 | 0.12 | 3.20 | 0.16 | 3.50 | 1.60 | |

 Table 7.6
 Final energy demand for the base case and the improvement options in kWh/m²a

a) for additional roof insulation and façade insulation, the final energy demand for the base case and the improvement options was calculated as an average over the residual service life of the building type (20, 30 or 40 years);

b) for the new sealings, the final energy demand for the base case and the improvement options was calculated for the first 10 years only

7.1.4 Quantifying the costs

Each measure entails both additional investments and cost savings as a result of fuel cost savings in the forthcoming years. The procedure used to evaluate the net costs of each improvement potential is shown in Figure 7.4.

The software epiqr[®] was used to calculate the costs for the improvement measures based on national cost data. For example, for the additional façade insulation, e.g. the cost for cleaning the existing facade including partial demolition of the existing cladding, then the implementation of an exterior thermal insulation composite system (insulation fixed with dowels, armour, cladding, and paint) and finally the cost for scaffolding were calculated. For the calculation of the costs incurred in the base case, the simple refurbishment of the façade along with cleaning, partial demolition of loose cladding, new cladding and paint including scaffolding were calculated. In both cases, the royalty cost for external planners and accessory charges were included.

The additional costs incurred in the improved case have to take into account both types of changes incurred as a result of the improvement measures and as a result of the refurbishment action that take place anyway in both the base case and the improved case as shown in, e.g. Figure 7.1.

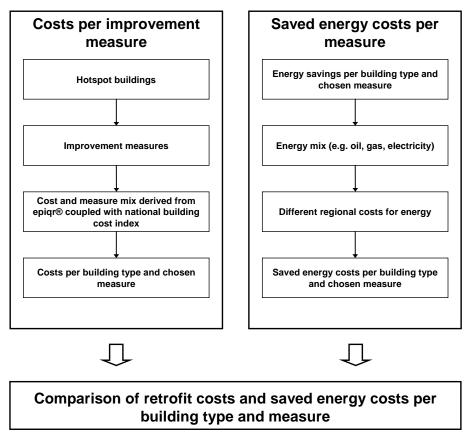

Figure 7.4 Procedure for the cost analysis

Each building type represents buildings in different European countries where construction and refurbishment costs vary as a result of different production costs (e.g. labour). Country-specific costs were derived by applying a building cost index. This country-specific building cost index is taken from [BKI 2007] where 1200 projects were analysed. The index is set to 1.0 for German buildings for the year 2007 (Figure 7.5). This means if, e.g. façade insulation costs on average 100 EUR in Germany (the price between the Polish border and Munich varies between 80 and 125 EUR) the same measure will cost on average 118 EUR in France as the French building cost index is 1.18 for 2007.

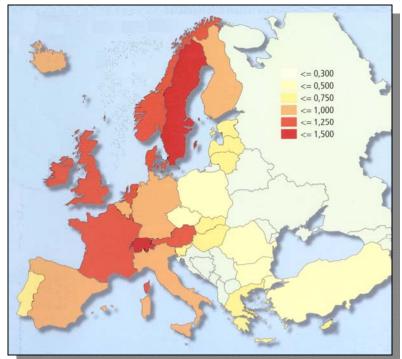

Figure 7.5 Building cost index in the European Union in 2007 [BKI 2007]

The costs per building type and country were then weighted according to their national representativeness to derive an average zone-specific price. The costs were also divided by the living area of the building type to calculate the prices per square metre (see Table 7.7).

| Table 7.7 Example for the costs per m ² for building types and measures in zone 1 (Euro) | | | | | | | |

 Table 7.7
 Example for the costs per m² for building types and measures in zone 1 (Euro)

The final energy demand estimates for the base case and improved cases (kWh/m^2a) were then multiplied by the energy cost per kWh to derive the fuel cost savings.

The average per kWh price was derived by taking into account the zone average energy mix and the national prices for each energy carrier. The price derived for zone 1 and zone 2 - zone 3 is not considered here - are respectively 0.054 €EUR/kWh and 0.051 EUR/kWh.

Two cost indicators were calculated (see Annex D for details): Net Present Value (NPV) and Internal Rate of Return (IRR). A discount rate of 4% and a yearly energy price increase of 2% was considered, which can be seen as a conservative approach.

7.1.5 Environmental improvement potential

This section presents the quantified environmental benefits of the improvement options for existing buildings. First, the environmental improvements are presented per building type and per m² living area and year. Then these potentials are rescaled at zone level.

As Chapter 6 showed that CO_2 emissions were a good proxy indicator for the majority of environmental impacts from existing buildings, the following results are limited to the greenhouse gas emissions. The results at building level per m² living area and year are given in Table 7.8 and Figure 7.6.

All retrofit measures can be seen to yield a significant net improvement compared to the base scenario, which varies depending on the building type and on the measure. For a majority of building types and retrofitting measures, the emissions are reduced by at least 20% when compared to the base case.

 Table 7.8
 Greenhouse gas emissions for the base case and the improvement options

a) for additional roof insulation and façade insulation, the final energy demand for the base case and the improvement options was calculated as an average over the residual service life of the building type (20, 30 or 40 years);

b) for the new sealings, the final energy demand for the base case and the improvement options was calculated for the first 10 years only

It can also be seen that, within one zone and one building type (SI, MF and HR respectively) the higher the original impacts of the building, the greater the environmental improvement potential. This is the case for the poorly insulated buildings. This also explains the broad range of emission reductions, from almost 3% (additional roof insulation for Z2_SI_007_ex) to 49% (new sealings to reduce ventilation for Z2_MF_005_ex).

For single-family houses, roof insulation represents the biggest improvement potentials, followed by additional façade insulation and - for zone 1 – then reduced ventilation. Regarding roof insulation, the results suggest that the range of emission reductions when compared to the base case is higher in zone 1 (13 to 37%) than in zone 2 (3 to 34%).

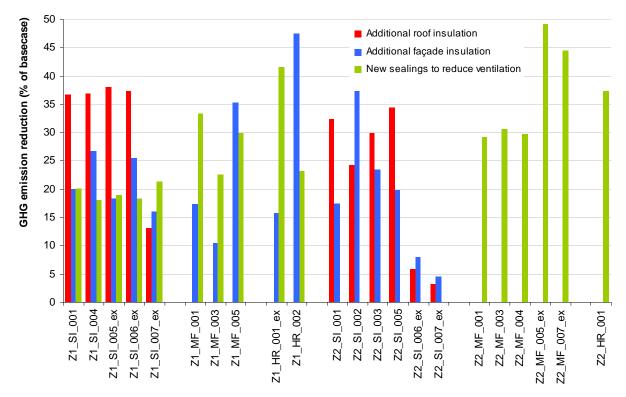

Figure 7.6 Relative environmental improvement potential for GHG emissions according to building type and measure

The environmental improvement potentials were rescaled to building stock level by multiplying the previous figures with the total living area of the respective building stock in the EU-25. This is shown in Table 7.9 and Figure 7.7. Figure 7.8 also presents the total environmental improvement potentials of the respective building type over the entire anticipated residual service life.

For some building types (especially those with significant environmental improvements and a significant share of the European building stock), the emissions reduction potential of the individual measures is very important (up to 34 Mt CO_2 -eq./a).

For each measure, the highest improvement potentials from the European perspective are derived for Zone 2, even though roof and façade are assumed to be further insulated only for single family houses. This is partly due to the larger building stock in play and to the colder climate conditions.

These results also confirm that the improvement potentials are bigger for roof insulation than for façade insulation. The highest environmental improvement potential for additional façade insulation can be observed for single-family houses in zone 2. It is also worth noting that in some cases, external wall insulation represents the biggest potential: for building type $Z2_SI_002$, the emissions reduction potential is estimated to be 23 Mt CO₂-eq./a, which is higher than that achievable with roof insulation.

New sealings to reduce ventilation can also lead to significant GHG emissions reduction potentials, especially for multi-family houses in zone 2 (up to 27 Mt CO₂-eq./a for building type Z2_MF_005_ex).

 Table 7.9
 Greenhouse gas emission savings for the improvement options compared to the base case

a) for additional roof insulation and façade insulation, the final energy demand for the base case and the improvement options was calculated as an average over the residual service life of the building type (20, 30 or 40 years);b) for the new sealings, the final energy demand for the base case and the improvement options was calculated for the first 10 years only

The improvement potentials were only calculated according to the mapping of the identified environmental hotspots and the considered existing building types (see Table 7.3). Thus,

blank cells do not mean that there is no reduction potential. These improvement options/building type combinations were just not assessed because the building element was not detected to be an environmental hotspot for the respective building type (e.g. roof for multi-family houses and high-rise buildings in zone 1) in the hotspot analysis (see Section 5.4).

From these results, it can be concluded that the major improvement potentials lie with single-, two-family and terrace houses, followed by multi-family houses. Considering high-rise buildings, despite important percentage reduction potentials, the smaller emissions reductions are expected in absolute terms due to the lower relevance of these building types in terms of the share of building stock.

When summed over all building types considered and respective measures, the total emissions reductions reach about 360 Mt CO₂-eq./a.

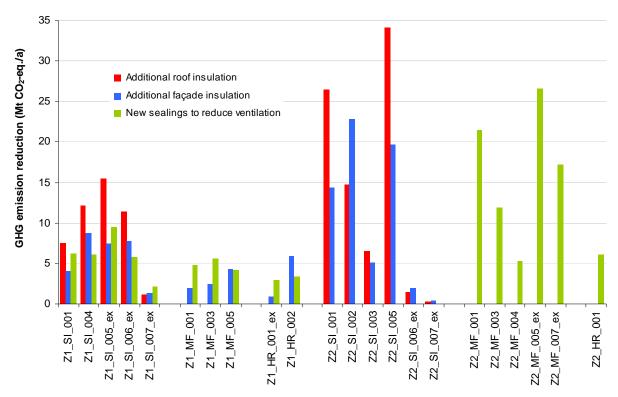

Figure 7.7 Total environmental improvement potential for GHG emissions according to building type and measure in the EU-25 per year

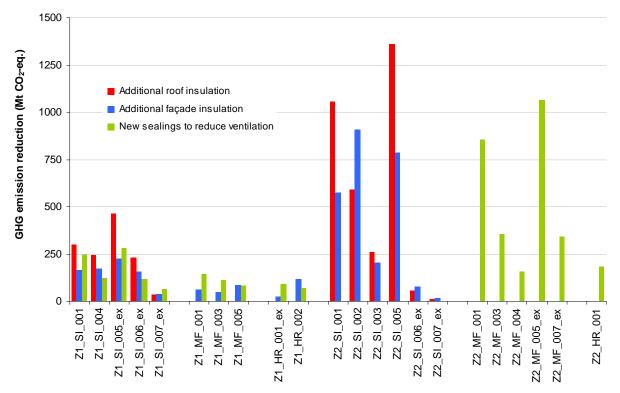

Figure 7.8 Total environmental improvement potential for GHG emissions according to building type and measure in the EU-25 over the total residual service life of the building type

7.1.6 Cost efficiency of the improvement options

Table 7.10 gives an overview of the cost assessment of the selected improvement action based on the internal rate of return – assuming a 2% annual increase of energy prices (see Annex D 2).

For **additional roof insulation**, only three building types show a negative internal rate of return, all other building types show high internal rates of return and therefore are preferable from an economic point of view.

Regarding **additional façade insulation**, 16 building types were identified for the measure to improve the external wall. Five building types show a negative internal rate of return. For the remaining nine building types, the internal rate of return is between 1.8% and 14.6%.

For **reduced ventilation losses**, as a result of the low investment costs when compared to the fuel cost savings, the internal rate of return is very high. It should be noted, however, that such a measure has to be implemented properly to avoid severe problems such as reduced indoor quality and moisture problems resulting from reduced air quality.

Overall, in a majority of cases (building types and improvement options), the measures analysed are cost efficient.

However, this general conclusion only holds true if the energy savings are granted to the investor. If the building is rented, the cost can hardly be transferred completely to the tenant. On the other hand, the tenant only benefits from the energy savings. Therefore the conclusion stated above only holds true if the investor also benefits from the energy cost reduction.

| Building type | Additional roof insulation | Additional façade insulation | Additional roof & façade insulation | New sealings to reduce ventilation | |

7.1.7 CO₂ abatement costs

Using the NPV of the improvement measures when compared to the base case (see Annex D), which, by definition, accounts for all the incurred life cycle costs (investment and fuel costs savings), the costs per unit of abated life cycle CO_2 emissions were calculated (abatement cost).

In Figure 7.9, the individual measures as applied to the considered building types were ranked according to the increasing abatement costs (shown by the vertical axis). The horizontal axis shows the cumulated emissions reduction potential at EU-25 level.

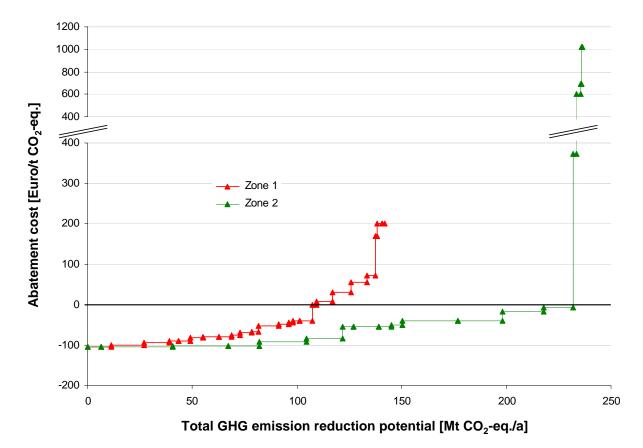

Figure 7.9 Abatement cost of the improvement measures related to the total GHG emission reduction potential for the EU-25

Figure 7.9 shows that most of the improvement options are feasible with a negative abatement cost, which means that the energy savings resulting from the measure outweigh the initial investment cost: 80% of the total GHG reduction potential in zone 1 and 95% of the potential in zone 2 can be realised in this way. Only a few improvement measures show positive abatement costs. For the measure "new sealings to reduce ventilation", the abatement costs turn out to be positive for one building only which, in addition, represents a low improvement potential (see Table 7.11). Regarding "additional roof insulation", most of the measures are cost efficient (see Table 7.10). They also come with a high total reduction potential for the EU-25.

The additional façade insulation shows comparably high CO_2 abatement costs with a medium reduction potential. Still, for most building types, the internal rate of return is positive (see Table 7.10).

In conclusion, the measures "additional roof insulation" and "new sealings to reduce ventilation losses" may be favourable both from the total environmental improvement potentials and from the efficiency in terms of costs of CO_2 abatement.

7.1.8 Socio-cultural impacts

Besides costs, the project has not quantified the socio-economic impacts of the improvement measures at EU level. Some indirect impacts of these measures can be identified as listed below:

- most of all the **thermal comfort** of the inhabitants is improved by insulation measures. As • the human body senses temperature by around two thirds through radiation exchange between the surrounding radiating surfaces, warmer surfaces (in winter time) caused by insulation of the wall and the roof cause greater thermal comfort
- the reduction of the ventilation losses and new windows can increase insulation against • noise
- the health of the inhabitants can be also be increased by higher surface temperatures of the inside of external wall as the mould and fungus growth is reduced. This may not be true for reduced moisture transport through reduced ventilation
- other functional or social aspects such as breaking down barriers for disabled or elderly persons, security, improved neighbourhood situation, etc. can't be attributed to the measures.

7.1.9 Conclusions

The three measures, roof insulation, façade insulation and reduced ventilation yield a significant environmental improvement potential, which, for a majority of buildings represents at least a 20% improvement when compared to the base case.

Additional roof insulation and new sealings to reduce ventilation represent the biggest potentials (about 130 Mt CO_2 -eq./a and 140 Mt CO_2 -eq./a respectively for the building types considered). The potential for roof insulation is particularly high for single-family houses. Both measures were shown to be applicable with economic profitability in most cases. The additional insulation of external walls also represents an important potential (about 110 Mt CO_2 -eq./a). In this case, however, the economic profitability is less systematic as, in some cases, the fuel costs savings do not compensate the higher initial investments.

For each measure, the highest improvement potentials from the European perspective are derived for zone 2. This is partly due to the larger building stock in play and to the colder climate conditions.

When summed over all building types considered and all respective measures, the total emissions reductions reach 360 Mt CO_2 -eq./a. The results have also shown that most of the improvement options are feasible with negative abatement costs.

The decision on which measure to take for an individual building can, to some extent, be guided from these results but the results also show the need to take account of the individual building situation before deciding on the priority measure.

7.2 New buildings

Regarding improvement options for new buildings, as explained in Section 6.2, the quantification of environmental benefits has been limited to the options that primarily reduce the impacts from the construction phase by changing the material composition of buildings.

The analysis was made by using the generic building model initially developed and used in Section 4.5. The alternatives were modelled in order to calculate the new resulting life cycle impact assessments (LCIA) and to be able to compare them with the base case ones. This was applied to four building types selected from the initial list of new buildings, and one example of each group of building types was selected (see Table 7.12).

| Z2_SI_008 | 366 | X | | Х | |

 Table 7.12
 New buildings selected for analysis with the construction elements considered for material substitution

For each of the four building types, alternative material compositions were selected:

- breeze concrete
- sandlime

- wooden construction
- cored brick
- reinforced concrete.

The alternative construction materials were assessed for exterior and interior walls, but not for floors/ceilings or basements. These alternatives have different environmental impacts and not all alternatives necessarily have a lower impact than the base scenario. This is illustrated in Figure 7.10 which compares four alternatives for exterior walls with the base scenario corresponding to the building type Z1_MF_004. This graph shows that three of the proposed alternatives have a reduced environmental profile when compared to the base scenario and that the alternative proposing reinforced concrete has an increased environmental profile. In addition, the only alternative which results in a significant improvement is the wood construction as, in this case, the life cycle greenhouse gas emissions are reduced by 12%.

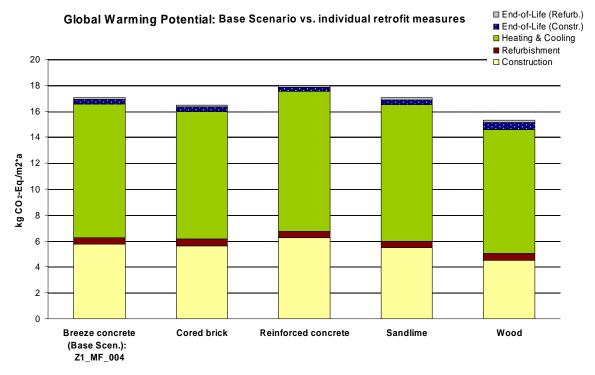

Figure 7.10 Example of results (greenhouse gas emissions) for new buildings (here: Z1_MF_004): comparison of base case (breeze concrete) to four alternative construction materials for exterior walls

All the results for the buildings considered and alternative construction materials in Table 7.13, show the total life cycle impacts relative to the corresponding baseline values. This table confirms the conclusions derived from the previous example.

It can generally be stated that the wooden construction alternative has the lowest environmental impacts. The other construction options may differ from each other but any systematic benefit that would result is not as obvious.

 Table 7.13
 Total life cycle impacts of the constructional alternatives compared to the base case

Although, wood appears to represent a better performing material from an environmental standpoint, it is, however, not as easy to derive an improvement potential at EU level. Extrapolating such results at EU level would indeed require further investigation of the construction options which better suit with the local and weather conditions – considering, amongst other things, thermal mass requirements. For this reason, the figures presented were not rescaled at EU level.

Another aspect which would need to be further investigated is the consideration of the upstream processes involved which includes the conditions for forest management. If the wood is taken from a forest under sustainable management, it can be assumed that the carbon balance is neutral for the atmosphere. If, on the other hand, the harvested wood is not compensated by continuous forest growth, it should be borne in mind that carbon is likely to be emitted to the atmospheres from, e.g. the soils. In such cases, the carbon balance would not be neutral and net emissions to the atmosphere have to be accounted for. The effects on biodiversity would also need to be further assessed.

8 Conclusions

This project analysed the life cycle impacts of residential buildings in Europe, identified the main sources of environmental impacts and assessed the environmental improvement potential.

A buildings typology was first defined, leading to a selection of 72 building types, amongst which there were 19 new building types. These were assessed to be representative for about 80% of the residential building stock in the EU-25. These buildings were described in terms of their building stock representativity, geographical distribution, size, age, design, material composition, residual lifespan, and thermal insulation.

8.1 Life cycle impacts

The derived buildings models were subjected to a life cycle assessment. In particular, the final energy demand for heating was calculated by using the standard calculation method, taking into account all determinant parameters (e.g. climate, indoor setting temperature, building geometry).

This first analysis emphasised the important role of energy use in most of the environmental impacts quantified, first as a result of fuel combustion for space heating, and, second, as a result of the industrial processes involved in the manufacturing of building products. Consequently, both primary energy use and GHG emissions are good proxy indicators to assess the environmental performance of the buildings.

New buildings, as currently erected, generally show better environmental performance than existing ones. This is due to the better energy performances achieved as long as the best available practices are applied, especially in terms of building insulation.

Weather conditions obviously entail higher space heating demands, which results in higher energy demand for buildings in northern European regions. However, when normalised to similar weather conditions (based on heating degree days), buildings in these zones tended to have the best energy performances. The effect of the buildings geometry was also reflected in the general trend of higher energy demand in single-family houses when compared to the others. Cooling demand was estimated to be currently negligible in the total building energy demand. The effect of the increase in cooling systems sales on the future cooling demand in buildings was, however, not analysed.

The use phase of buildings, as dominated by energy demand for heating is by far the highest for all buildings. For new buildings, the construction phase is also significant and its relative importance varies from one impact category to the other. The end-of-life phase is of much lower importance. The environmental impacts from the use phase were broken down into the different building elements based on the respective heat losses. This showed that heat losses resulting from ventilation and infiltration are of significant importance for all buildings. This also holds true for external walls, particularly for high-rise buildings. Heat losses through roofs are important for a majority of single-family and multi-family houses. Windows were suggested to be of lower importance. This is partly because the retrofitting of windows was assumed to be part of autonomous improvement, which may, to some extent, provide a too optimistic picture. In general, the variations observed from one building type to the other are explained by the geometry and current insulation level of the building. 8

The use phase was also shown to be the most important one for new buildings with, however, a lower relative importance as a result of the better energy performance of these buildings. Besides this, the construction phase is of second importance, especially related to the exterior walls, the basement, and floors/ceilings. Interior walls, roofs and windows only play a minor role.

8.2 Improvement options

Improvement options for relevant building types were identified, focusing on the environmental hotspots (use phase and construction phase). They were analysed against the base cases that were initially defined.

For the reasons given in Section 6.2.1 regarding **new building types**, the quantification of environmental benefits has been limited to the options that primarily reduce the impacts from the construction phase by changing the material composition of the buildings.

The results showed that, amongst the alternatives considered, significant environmental improvements can be expected only when the substitution leads to the use of wood products instead of more "conventional" products (concrete, reinforced concrete, bricks).

For **existing buildings** the measures are consistent with the dominant role of the use phase, addressing this life cycle part, and particularly space heating, whenever the corresponding building element was shown to be an environmental hotspot. The three measures, "additional roof insulation", "additional façade insulation", and "new sealings to reduce ventilation" yield a significant environmental improvement potential, which, for a majority of the buildings types analysed represent at least a 20% improvement compared to the base case.

When rescaled at the EU-25 level, the resulting improvement potentials as measured in terms of CO_2 emission reductions is high. For each measure, the highest improvement potentials from the European perspective are derived for Zone 2. This is partly due to the larger building stock in play and to the colder climate conditions.

The major improvement potentials are found with single-, two-family and terrace houses, followed by multi-family buildings. Despite important percentage reductions potentials for high-rise buildings, smaller emissions reductions are expected in absolute terms due to the smaller share of these buildings in the overall building stock.

When combining and totalling the building types and relevant retrofit measures, the derived total life cycle CO_2 emissions reductions potential reaches 360 Mt CO_2 -eq/a which corresponds to about 7% of the total direct greenhouse gas emissions in the EU-25 in 2005 (without land use, land use change and forestry) [EEA 2007]. This high emissions reductions potential estimation can be achieved provided that all barriers (e.g. social, economic) are overcome. The initial investment costs may represent one of these barriers. These life cycle costs of the retrofit measures were analysed through the calculated internal return rates and the net present values associated with these retrofit measures.

For both roof insulation and reduced ventilation, the measures were shown to be economically profitable (positive internal return rate) for a majority of buildings (see Table 8.1). For external wall insulation, the economic profitability is less systematic as, in some cases, the subsequent fuel costs savings do not compensate the higher initial investments. When compared to the two other measures, the application of new sealings in order to reduce ventilation bears smaller improvement potentials but has a higher economic profitability as a result of very low initial investments.

It was also shown that most of the improvement options are feasible with a negative CO_2 abatement cost: 80% of the total GHG reductions potential in zone 1 and 95% of the potential in zone 2.

| Improvement measure | Building group | Zone | Abatement cost | Total improvement potential |
|------------------------|----------------------|--------|-----------------------------|--------------------------------|
| | | | Euro/t CO ₂ -eq. | Mt CO ₂ -eq./a |
| Additional roof | Single-family houses | Zone 1 | -90 | 48.67 |
| insulation | | Zone 2 | -93 | 83.50 |
| Additional | Single-family houses | Zone 1 | 55 | 29.46 |
| façade insulation | 1 | Zone 2 | -19 | 64.21 |
| | Multi-family houses | Zone 1 | 12 | 8.67 |
| | | Zone 2 | Na | na |
| | High-rise buildings | Zone 1 | -56 | 6.81 |
| | | Zone 2 | Na | na |
| New sealings to | Single-family houses | Zone 1 | -60 | 29.71 |
| reduce | | Zone 2 | Na | na |
| ventilation | Multi-family houses | Zone 1 | -65 | 14.48 |
| | | Zone 2 | -53 | 82.39 |
| | High-rise buildings | Zone 1 | -54 | 6.39 |
| | | Zone 2 | -55 | 6.06 |

| Table 8.1 | Summary of environmental improvement potential and abatement costs |
|-----------|--|
|-----------|--|

These general conclusions provide elements to guide policy making aimed to support the implementation of these measures with instruments such as subsidies, and consumer awareness. However, the decision on which measure to apply for an individual building should be based on a prior assessment which should take into account the individual situation of the building.

8.3 Key message

Summarising, it can be stated that the current situation of the European residential building stock in terms of environmental performance is far from the currently discussed low-energy standards and there is a tremendous potential for improvements. If the measures examined are carried out on the buildings considered, the emissions of greenhouse gasses from these buildings may be cut by around 30 to 50% over the next 40 years. Therefore, active promotion and strong actions from all stakeholders have to be undertaken in order to seize this environmental opportunity. The information in this study provides the basis for discussions on measures and steps that can be taken in that direction.

Annex B Detailed technical description of all building types

The tables in this annex describe all identified building types on a technical level, providing all relevant background information used to conduct the construction materials-based parts of the Life Cycle Assessment. For this purpose, all building types are divided into the same construction elements. Whenever refurbishment takes place, this fact is highlighted in yellow.

| Zone Type and number | Construction/ description | Material | Residual Service Life | Refurbishment Factor | Density (kg/m ³) | Thickness (m) | Area (m²) | Volume (m ³) | Piece | Mass (kg, St) | Mass (t) |

Annex C Life Cycle Impact Assessment results for all building types

This annex delivers all necessary information to characterize the building types on a building level (not on a materials-level) and the results of the Life Cycle Assessments for each building type.

For each building type, two pages are provided. Page one displays the information to characterize the building type. Page two presents a table providing the data to identify the contributions of life cycle phases, construction elements and building aspects to the total impacts of the building type as well as a graph displaying the contribution of the construction elements and building aspects for Primary Energy use (total) per m^2 and year.

Annex C 1 Building type Z1_SI_001

Single-family house Brick masonry, wooden flooring, pitched roof

Annex D Cost indicators

Annex D 1 Net present value (NPV)

The net present value (NPV) calculation is the most common dynamical cost calculation method. It takes into account the income and cost for each following period multiplied by a discount factor. The discount factor contains the adequate target or discount rate. An easy explanation of the net present value and the adequate target rate is as follows: If one has the choice to invest money or to bring the money to the bank and get an interest rate of 4%, then the adequate target rate is assumed to be 4%. Calculating the net present value with this adequate target rate the following results might occur:

Net present value = 0The investment is as good as taking the money to the bankNet present value > 0The investment is better then the alternative (money to the bank)Net present value < 0</td>The investment should not be done, as it is better to bring the money to the bank

The formula to calculate the net present value *NPV* is as follows:

$$NPV = -C_0 + \sum_{t=1}^{n} \frac{C_t}{(1+r)^t}$$

2)

 C_0 Initial investment (i.e. the refurbishment action)

t Time of the cash flow (year)

n Total time of the project (here: residual service life of the building)

 C_t Expected net cash flow (expected income in time t minus expected expense in time t)

r Discount rate (4%)

When calculating this cost indicator for the improvement options, the initial investment C_0 was calculated as the additional cost for the improvement measure compared to the alternative. The net cash flow C_t was assumed to be the cost of the energy saved for each respective year *t*.

The energy costs might increase in the next years. This was reflected by assuming a moderate increase of the energy cost by 2% per year.

Annex D 2 Internal rate of return

The internal rate of return (*IRR*) is the reverse calculation of the NPV. That means, to calculate the adequate target rate (see previous section) that would be necessary to yield a netpresent value equal to zero. Therefore, it can be understood as yield for the investment:

$$0 = -C_0 + \sum_{t=1}^{n} \frac{C_t}{(1 + IRR)^t}$$
3)

 C_0 Initial investment (i.e. the refurbishment action)

- *t* Time of the cash flow (year)
- *n* Total time of the project (here: residual service life of the building)

 C_t Expected net cash flow (expected income in time t minus expected expense in time t)

Annex E Reference list for the definition of building types in the EU-25

This annex provides the list of the literature that has been used to characterize the European residential building stock. This literature is the basis for the definition of the building types used in this study.

EUR 23493 EN – Joint Research Centre – Institute for Prospective Technological Studies Title: Environmental Improvement Potential of Residential Buildings.... Authors: Françoise Nemry & Andreas Uihlein Luxembourg: Office for Official Publications of the European Communities 2008 EUR – Scientific and Technical Research series – ISSN 1018-5593 ISBN 978-92-79-09767-6 ISSN 1018-5593

Abstract

This report on "Environmental improvement potential of residential buildings" is a JRC's scientific contribution to the European Commission's Integrated Product Policy framework which seeks to minimise the environmental degradation caused the life cycle of products. A previous study coordinated by the JRC (EIPRO study) had shown that building occupancy and structure all together make up 20 to 35% of the impacts of all products for most impact categories.

This report presents a systematic overview of the environmental life cycle impacts of residential buildings in EU-25. It also provides an analysis of the technical improvement options that could be help reducing these environmental impacts, with a special focus to their main source, namely energy use for space heating. The report assesses the environmental benefits and the costs associated with these improvement options.

How to obtain EU publications

Our priced publications are available from EU Bookshop (http://bookshop.europa.eu), where you can place an order with the sales agent of your choice.

The Publications Office has a worldwide network of sales agents. You can obtain their contact details by sending a fax to (352) 29 29-42758.

The mission of the JRC is to provide customer-driven scientific and technical support for the conception, development, implementation and monitoring of EU policies. As a service of the European Commission, the JRC functions as a reference centre of science and technology for the Union. Close to the policy-making process, it serves the common interest of the Member States, while being independent of special interests, whether private or national.
